**Adventitial Cystic Disease of the Popliteal Artery.** The first successful operative repair of popliteal artery occlusion caused by a cyst arising from the adventitia was reported in 1954 by Ejrup and Hierton. Adventitial cystic disease is a rare arterial condition occurring at an incidence of 0.1%, usually in the popliteal artery. This disease affects men in a ratio of approximately 5:1 and appears predominantly in the fourth and fifth decades. The incidence is approximately 1 in 1200 cases of claudication or 1 in 1000 peripheral arteriograms. The precedence of reported cases is found in Japan and Europe. However, this disease may affect other vascular sites, such as the femoral, external iliac, radial, ulnar, and brachial arteries. Besides claudication as a symptom, this diagnosis should be considered in young patients who have a mass in a nonaxial vessel in proximity to a related joint. These synovial-like, mucin-filled cysts reside in the subadventitial layer of the vessel wall and have a similar macroscopic appearance to ganglion cysts. Despite this similarity and suggestion of a joint origin for these lesions, histochemical markers have failed to link the cystic lining to synovium.

Patients presenting at a young age with bilateral lower extremity claudication and minimal risk factors for atheromatous formation should be evaluated for adventitial cystic disease, as well as the other two nonatherosclerotic vascular lesions described here. Because of luminal encroachment and compression, peripheral pulses may be present in the limb when extended, but then can disappear during knee joint flexion. Noninvasive studies may suggest arterial stenosis with elevated velocities. Color-flow duplex scanning followed by T2-weighted MRI now appears to be the best diagnostic choice. Angiography will demonstrate a smooth, well-defined, crescent-shaped filling defect, the classic "scimitar" sign. There may be associated calcification in the cyst wall and no other evidence of atherosclerotic occlusive disease.

Various therapeutic methods have been described for the treatment of adventitial cystic disease. The recommended treatments are excision of the cyst with the cystic wall, enucleation, or simple aspiration when the artery is stenotic. Retention of the cystic lining leads to continued secretion of the cystic fluid and recurrent lesions. In 30% of patients who have an occluded artery, resection of the affected artery, followed by an interposition graft using autogenous saphenous vein, is recommended.

**Popliteal Artery Entrapment Syndrome.** Love and colleagues first coined the term popliteal artery entrapment in 1965 to describe a syndrome combining muscular involvement with arterial ischemia occurring behind the knee, with the successful surgical repair having taken place 6 years earlier. This is a rare disorder with an estimated prevalence of 0.16% that occurs with a male-to-female ratio of 15:1. Five types of anatomic entrapment have been defined, according to the position of the medial head of the gastrocnemius muscle, abnormal muscle slips or tendinous bands, or the course of the popliteal artery itself (Table 23-29). Concomitant popliteal vein impingement occurs in up to 30% of cases. Twenty-five percent of cases are bilateral.

The typical patient presents with swelling and claudication of isolated calf muscle groups following vigorous physical activity. Various differential diagnoses must be considered when encountering patients with symptoms and signs suggestive of popliteal artery entrapment syndrome (Table 23-30). In a large series of 240 patients, the median age for surgical treatment was 28.5 years. Noninvasive studies with ABIs should be performed with the knee extended and the foot in a neutral, forced plantar, and dorsiflexion position. A drop in pressure of 50% or greater or dampening of the plethysmographic waveforms in plantar or dorsi-flexion is a classic finding.

| Table 23-29 Classification of popliteal entrapment syndrome |
|---------------------------------|----------------------------------|
| **TYPE**                       | **DESCRIPTION**                  |
| I                              | Popliteal artery is displaced medially around a normal medial head of the gastrocnemius |
| II                             | Medial head of gastrocnemius, which arises lateral to popliteal artery |
| III                            | Popliteal artery is compressed by an accessory slip of muscle from medial head of gastrocnemius |
| IV                             | Entrapment by a deeper popliteus muscle |
| V                               | Any of the above plus popliteal vein entrapment |
| VI                             | Functional entrapment |

| Table 23-30 Differential diagnosis for popliteal entrapment syndrome |
|---------------------------------|----------------------------------|
| **Vascular Etiologies**         | **Musculoskeletal Etiologies**   |
| Atherosclerosis                 | Gastrocnemius or soleus strain   |
| Buerger's disease               | Periostitis                      |
| Trauma                          | Compartment syndrome            |
| Popliteal aneurysm              | Stress fractures                 |
| Adventitial cystic disease      | Tibialis posterior tendonitis    |
| Extrinsic compression           | Muscular anomalies               |
| Cardiac embolism                |                                     |
| Deep vein thrombosis            | **General Neurologic Etiologies** |
| Venous entrapment               | Spinal stenosis                  |

**General Neurologic Etiologies**
Contraction of the gastrocnemius should compress the entrapped popliteal artery. The sudden onset of signs and symptoms of acute ischemia with absent distal pulses is consistent with popliteal artery occlusion secondary to entrapment. Other conditions resulting from entrapment are thrombus formation with distal emboli or popliteal aneurysmal degeneration. Although CT and MRI have been employed, angiography remains the most widely used test. Angiography performed with the foot in a neutral position may demonstrate classical medial deviation of the popliteal artery or normal anatomic positioning. Coexisting abnormalities may include stenosis, luminal irregularity, delayed flow, aneurysm, or complete occlusion. Diagnostic accuracy is increased with the use of ankle stress view-active plantar flexion and passive dorsiflexion.

The treatment of popliteal artery entrapment consists of surgical decompression of the impinged artery with possible arterial reconstruction. Division of the anomalous musculotendinous insertion site with or without saphenous vein interposition grafting to bypass the damaged arterial segment has been described to be the procedure of choice. The natural history of entrapment is progressive arterial degeneration leading to complete arterial thrombosis. In such instances, thrombolytic therapy is needed with subsequent release of the functional arterial impairment. Lysis will improve distal runoff and may improve limb-salvage and bypass patency rates.

**Buerger’s Disease (Thromboangiitis Obliterans)**

Buerger’s disease, also known as thromboangiitis obliterans, is a progressive nonatherosclerotic segmental inflammatory disease that most often affects small- and medium-sized arteries, veins, and nerves of the upper and lower extremities. The clinical and pathologic findings of this disease entity were published in 1908 by Leo Buerger in a description of 11 amputated limbs. The typical age range for occurrence is 20 to 50 years, and the disorder is more frequently found in males who smoke. The upper extremities may be involved, and a migratory superficial phlebitis may be present in up to 16% of patients, thus indicating a systemic inflammatory response. In young adults presenting to the Mayo Clinic (1953–1981) with lower limb ischemia, Buerger’s disease was diagnosed in 24%. Conversely, the diagnosis was made in 9% of patients with ischemic finger ulcers. The cause of thromboangiitis obliterans is unknown; however, use of or exposure to tobacco is essential to both the diagnosis and progression of the disease.

Pathologically, thrombosis occurs in small- to medium-sized arteries and veins with associated dense polymorphonuclear leukocyte aggregation, microabscesses, and multinucleated giant cells. The chronic phase of the disease shows a decrease in the hypercellularity and frequent recanalization of the vessel lumen. End-stage lesions demonstrate organized thrombus and blood vessel fibrosis. Although the disease is common in Asia, North American males do not appear to have any particular predisposition, as the diagnosis is made in less than 1% of patients with severe limb ischemia.

Buerger’s disease typically presents in young male smokers, with symptoms beginning prior to age 40. Patients initially present with foot, leg, arm, or hand claudication, which may be mistaken for joint or neuromuscular problems. Progression of the disease leads to calf claudication and eventually ischemic rest pain and ulcerations on the toes, feet, or fingers. A complete history should exclude diabetes, hyperlipidemia, or autoimmune disease as possible etiologies for the occlusive lesions. Because it is likely that multiple limbs are involved, angiography should be performed of all four limbs. Even if symptoms are not yet present in a limb, angiographic findings may be demonstrated. Characteristic angiographic findings show disease confinement to the distal circulation, usually infrapopliteal and distal to the brachial artery. The occlusions are segmental and show “skip” lesions with extensive collateralization, the so-called “cork-screw collaterals.”

The treatment of thromboangiitis obliterans revolves around strict smoking cessation. In patients who are able to abstain, disease remission is impressive and amputation avoidance is increased. In the experience reported from the Oregon Health Sciences Center, no disease progression with associated tissue loss occurred after discontinuation of tobacco. The role of surgical intervention is minimal in Buerger’s disease, as there is often no acceptable target vessel for bypass. Furthermore, autogenous vein conduits are limited secondary to coexisting migratory thrombophlebitis. Mills and associates reported their results of 31% limb loss in 26 patients over 15 years, thus authenticating the virulence of Buerger’s disease involving the lower extremities. In addition, others have described a significant discrepancy in limb loss in patients who continued to smoke versus those who discontinued tobacco use (67% vs. 35%).

VENOUS ANATOMY

Veins are part of a dynamic and complex system that returns low-nutrient deoxygenated blood to the heart. Venous blood flow is dependent on multiple factors such as gravity, venous valves, the cardiac and respiratory cycles, blood volume, and the calf muscle pump. Alterations in the intricate balance of these factors can result in venous pathology.

Structure of Veins

Veins are thin-walled, highly distensible, and collapsible. Their structure specifically supports the primary functions of veins to transport blood toward the heart and serve as a reservoir to prevent intravascular volume overload.

The venous intima is composed of a nonthrombogenic endothelium with an underlying basement membrane and an elastic lamina. The endothelium produces endothelium-derived relaxing factors such as nitric oxide and prostacyclin, which help maintain a nonthrombogenic surface through inhibition of platelet aggregation and promotion of platelet disaggregation. Circumferential rings of elastic tissue and smooth muscle located in the media of the vein allow for changes in vein caliber with minimal changes in venous pressure. The adventitia is most prominent in large veins and consists of collagen, elastic fibers, and fibroblasts. When a vein is maximally distended, its diameter may be several times greater than that in the supine position.

In the axial veins, unidirectional blood flow is achieved with multiple venous valves. The inferior vena cava (IVC), common iliac veins, portal venous system, and cranial sinuses are valveless. In the axial veins, valves are more numerous distally in the extremities than proximally. Each valve consists of two thin cusps of a fine connective tissue skeleton covered by endothelium. Venous valves close in response to cephalad-to-caudal blood flow at a velocity of at least 30 cm/s.

Lower Extremity Veins

Lower extremity veins are divided into superficial, deep, and perforating veins. The superficial venous system lies above the uppermost fascial layer of the leg and thigh and consists of the great saphenous vein (GSV) and small saphenous vein (SSV) and their tributaries. The GSV originates from the dorsal pedal venous arch and courses cephalad, anterior to the medial malleolus, entering the common femoral vein approximately 4 cm inferior and lateral to the pubic tubercle. The saphenous nerve accompanies the GSV medially from the ankle to the level of the knee and supplies cutaneous sensation to the medial leg and ankle. The SSV originates laterally from the dorsal pedal venous arch and courses cephalad in the posterior calf. Most often, it penetrates the popliteal fossa, between the medial and lateral heads of the gastrocnemius muscle, to join the popliteal vein. The termination of the SSV may be quite variable, however, with a proximal extension of the SSV (the vein of Giacomini) frequently connecting with the deep femoral vein or GSV. The sural nerve accompanies the SSV laterally along its course and supplies cutaneous sensation to the lateral malleolar region.

The deep veins follow the course of major arteries in the extremities. In the lower leg, paired veins parallel the course of the anterior tibial, posterior tibial, and peroneal arteries, to join behind the knee forming the popliteal vein. Venous bridges connect the paired veins in the lower leg. The popliteal vein continues through the adductor hiatus to become the femoral vein. In the proximal thigh, the femoral vein joins with the deep femoral vein to form the common femoral vein, becoming the external iliac vein at the inguinal ligament.

Multiple perforator veins traverse the deep fascia to connect the superficial and deep venous systems. Potentially clinically important perforator veins are the Cockett and Boyd perforators. The Cockett perforator veins drain the medial...
lower leg and are relatively constant. They connect the posterior arch vein (a tributary to the GSV) and the posterior tibial vein. They may become varicose or incompetent in venous insufficiency states. The Boyd perforator veins connect the GSV to the deep veins approximately 10 cm below the knee and 1 to 2 cm medial to the tibia.

Venous sinuses are thin-walled, large veins located within the substance of the soleus and gastrocnemius muscles. These sinuses are valveless and are linked by valved, small venous channels that prevent reflux. A large amount of blood can be stored in the venous sinuses. With each contraction of the calf muscle bed, blood is pumped out through the venous channels into the main conduit veins to return to the heart.

**Upper Extremity Veins**

As in the lower extremity, there are deep and superficial veins in the upper extremity. Deep veins of the upper extremity are paired and follow the named arteries in the arm. Superficial veins of the upper extremity are the cephalic and basilic veins and their tributaries. The cephalic vein originates at the lateral wrist and courses over the ventral surface of the forearm. In the upper arm, the cephalic vein terminates in the infraclavicular fossa, piercing the clavipectoral fascia to empty into the axillary vein. The basilic vein runs medially along the forearm and penetrates the deep fascia as it courses past the elbow in the upper arm. It then joins with the deep brachial veins to become the axillary vein. The median cubital vein joins the cephalic and the basilic veins on the ventral surface of the elbow.

The axillary vein becomes the subclavian vein at the lateral border of the first rib. At the medial border of the scalenus anterior muscle, the subclavian vein joins with the internal jugular vein to become the brachiocephalic vein, with the subclavian vein coursing anterior to the scalenus anterior muscle. The left and right brachiocephalic veins join to become the superior vena cava, which empties into the right atrium.

**Key Points**

1. Thrombolytic therapy, surgical thrombectomy, and placement of inferior vena cava filters are adjunctive treatments that may be indicated in patients with extensive and complicated venous thromboembolism.
2. Deep vein thrombosis (DVT) and pulmonary embolism are frequent complications after major abdominal and orthopedic procedures. The risk is further increased in patients with malignancy and a history of venous thromboembolism. Options for DVT prophylaxis include intermittent pneumatic compression, use of graduated compression stockings, and administration of low-dose unfractionated heparin, low molecular weight heparin, fondaparinux, and vitamin K antagonists. However, prophylaxis should be stratified based on the patient’s level of risk.
3. In patients with established DVT, unfractionated heparin, low molecular weight heparin, and fondaparinux are options for initial antithrombotic therapy. The duration and type of long-term anticoagulation should be stratified based on the provoked or unprovoked nature of the DVT, the location of the DVT, previous occurrence of DVT, and presence of concomitant malignancy.
4. Saphenous vein stripping, endovenous laser treatment, and radiofrequency ablation are effective therapies for patients with saphenous vein valvular insufficiency. Concomitant varicose veins may be managed with compression therapy, sclerotherapy (for smaller varices), and phlebectomy.
5. The mainstay of treatment for chronic venous insufficiency is compression therapy. Sclerotherapy, perforator vein ligation, and venous reconstruction may be indicated in patients in whom conservative management fails.
6. Lymphedema is categorized as primary (with early or delayed onset) or secondary. The goals of treatment are to minimize edema and prevent infection. Lymphatic massage, sequential pneumatic compression, use of compression garments, and limb elevation are effective forms of therapy.

**EVALUATION OF THE VENOUS SYSTEM**

**Clinical Evaluation**

Evaluation of the venous system begins with a detailed history and physical examination. Risk factors for acute and chronic venous disease are identified. They include increased age, history of venous thromboembolism (VTE), malignancy, trauma and spinal cord injury, hospitalization and immobilization, obesity, nephrotic syndrome, pregnancy and the recently postpartum state, oral contraceptive use or hormone replacement therapy, varicose veins, and hypercoagulable states, as well as the postoperative state. Venous pathology is often, but not always, associated with visible or palpable signs that can be identified during the physical examination. There is variation among individuals in the prominence of superficial veins when the person is standing (Fig. 24-1). The superficial veins of a

![Figure 24-1. Varicose vein demonstrating evidence of chronic venous insufficiency.](image)
lean athletic person, even when normal, will appear large and easily visualized, but these veins will be far less obvious in the obese individual. Possible signs of superficial venous abnormalities are listed in Table 24-1. The deep veins cannot be directly assessed clinically, and abnormalities within them can only be inferred indirectly from changes found on clinical examination.

Chronic venous insufficiency (CVI) may lead to characteristic changes in the skin and subcutaneous tissues in the affected limb. CVI results from incompetence of venous valves, venous obstruction, or both. Most CVI involves venous reflux, and severe CVI often reflects a combination of reflux and venous obstruction. It is important to remember that although CVI originates with abnormalities of the veins, the target organ of CVI is the skin, and the underlying physiologic and biochemical mechanisms leading to the cutaneous abnormalities associated with CVI are poorly understood. A typical leg affected by CVI will be edematous, with edema increasing over the course of the day. The leg may also be indurated and pigmented with eczema and dermatitis. These changes are associated with excessive proteinaceous capillary exudate and deposition of a pericapillary fibrin cuff that may limit nutritional exchange. In addition, an increase in white blood cell trapping within the skin microcirculation in CVI patients may lead to microvascular congestion and thrombosis. Subsequently, white blood cells may migrate into the interstitium and release necrotizing lysosomal enzymes, potentially leading to tissue destruction and eventual ulceration.

Fibrosis can eventually develop from impaired nutrition, chronic inflammation, and fat necrosis (lipodermatosclerosis). Hemosiderin deposition due to the extravasation of red cells and subsequent lysis in the skin contributes to the characteristic pigmentation of chronic venous disease (Fig. 24-2). Ulceration can develop with longstanding venous hypertension and is associated with alterations in microcirculatory and cutaneous lymphatic anatomy and function. The most common location of venous ulceration is approximately 3 cm proximal to the medial malleolus (Fig. 24-3).

Trendelenburg’s test is a clinical test, historically important but now rarely used, that can help determine whether incompetent valves are present and in which of the three venous systems (superficial, deep, or perforator) the valves are abnormal. There are two components to this test. First, with the patient supine, the leg is elevated 45° to empty the veins, and the GSV is occluded with the examiner’s hand or with a rubber tourniquet. With the GSV still occluded, the patient stands and the superficial veins are observed for blood filling. The compression on the GSV is released and the superficial veins are observed for filling with blood. A negative result, indicating no clinically relevant venous reflux, is the gradual filling of the veins from arterial inflow. A positive result is the sudden filling of veins with standing while the GSV remains occluded indicating incompetent perforator

Figure 24-3. Venous ulceration located proximal to the medial malleolus.
and deep veins. The GSV valves are incompetent if the second component of the test yields a positive result. Interpretation of the findings of Trendelenburg’s test is subjective, and therefore, it has largely been supplanted by the more objective noninvasive vascular laboratory tests to localize sites of venous reflux.

**Noninvasive Evaluation.** Before the development of vascular ultrasound, noninvasive techniques to evaluate the venous system were based on plethysmographic techniques. Although a variety of plethysmographic techniques are used in the evaluation of both acute and chronic venous disease, they are all based on the detection of volume changes in the limb in response to blood flow. Duplex ultrasonography (DUS) augmented by color flow imaging is now the most important noninvasive diagnostic method in the evaluation of the venous system. DUS has become standard for the detection of infrainguinal deep vein thrombosis (DVT), with near 100% sensitivity and specificity in symptomatic patients. It is also the preferred method of evaluation for upper extremity venous thrombosis and is useful in the evaluation of CVI by documenting the presence of valvular reflux and venous obstruction. Overlying bowel gas and large body habitus make DUS less applicable to evaluation of intra-abdominal veins. Magnetic resonance venography (MRV) and computed tomography (CT) venography are noninvasive techniques for evaluation of pelvic and intra-abdominal veins.

**Invasive Evaluation.** Improved accuracy of noninvasive techniques for diagnostic purposes has made the use of invasive procedures more selective. Both venography and intravascular ultrasound (IVUS) are used as adjuncts to percutaneous or open surgical treatment of venous disorders. When planning endovascular or open surgical treatment, venography may be used to identify areas of obstruction in infrainguinal, intra-abdominal, and upper extremity veins, as well as reflux in intra-abdominal and infrainguinal veins. IVUS, with access generally via the common femoral vein, is used primarily to assess for occlusive lesions of the iliac veins and appears more sensitive than venography in detecting iliac vein obstruction.

Complications of venography include pain, thrombosis, or hematoma at the puncture site. Pain is lower with nonionic low-osmolality contrast media than with conventional contrast agents (with 18% vs. 44% of patients experiencing discomfort, respectively). Systemic effects of iodinated contrast media include allergic reaction and risk of renal failure. Postvenography venous thrombosis occurs distal to the venous puncture site in 1% to 9% of patients undergoing venography secondary to intimal damage from the intravenous (IV) contrast agent. Complications of IVUS are primarily related to the access site.

**VENOUS THROMBOEMBOLISM**

**Epidemiology**

Despite increased awareness and use of prophylactic modalities, DVT and pulmonary embolism (PE), or VTE, remain important preventable sources of morbidity and mortality, especially in the surgical patient. The incidence of VTE is approximately 100 per 100,000 people per year in the general population, with 20% of the diagnoses made within 3 months of a surgical procedure. Of the symptomatic patients, one third will present with PE and two thirds with DVT. The estimated number of cases of VTE may well be over 600,000 per year in the United States, making it a major U.S. health problem. Furthermore, death occurs in 6% of DVT and 12% of PE cases within 1 month of diagnosis.

**Risk Factors**

Three conditions, first described by Rudolf Virchow in 1862, contribute to VTE formation: stasis of blood flow, endothelial damage, and hypercoagulability. Of these risk factors, relative hypercoagulability appears most important in most cases of spontaneous VTE, or so-called idiopathic VTE, whereas stasis and endothelial damage likely play a greater role in secondary VTE, or so-called provoked VTE, occurring in association with transient risk factors such as immobilization, surgical procedures, and trauma. Identifiable risk factors for VTE generally relate to one of the conditions described by Virchow. Often more than one risk factor is present. Specific risk factors for VTE are listed in Table 24-2.

The more common acquired VTE risk factors include older age (>40 years), hospitalization and immobilization, hormone replacement and oral contraceptive therapy, pregnancy and the recently postpartum state, prior VTE, malignancy, major surgery, obesity, nephrotic syndrome, trauma and spinal cord injury, long-haul travel (>6 hours), varicose veins, antiphospholipid syndrome, myeloproliferative disorders, and polycythemia. Heritable risk factors include male sex, factor V Leiden

DVT = deep vein thrombosis; INR = international normalized ratio; LDUH = low-dose unfractionated heparin; LMWH = low molecular weight heparin; VTE = venous thromboembolism.

From the common femoral through the popliteal vein, the primary method of detecting DVT with ultrasound is demonstration of the lack of compressibility of the vein with probe pressure on B-mode imaging. Normally, in transverse section, the vein walls should coapt with pressure. Lack of coaptation indicates thrombus. Calf vein thrombi are often best detected by abnormalities in color flow imaging.

The examination begins at the ankle and continues proximally to the groin. Each vein is visualized, and the flow signal is assessed with distal and proximal compression. Lower extremity DVT can be diagnosed by any of the following DUS findings: lack of spontaneous flow (Fig. 24-6), inability to compress the vein (Fig. 24-7), absence of color filling of the lumen by color flow DUS, loss of respiratory flow variation, and venous distention. Again, lack of venous compression on B-mode imaging is the primary diagnostic variable. Several studies comparing B-mode ultrasound to venography for the detection of femoropopliteal DVT in patients clinically suspected to have DVT report sensitivities of >91% and specificities of >97%.20,21 The ability of DUS to assess isolated calf vein DVT varies greatly, with sensitivities ranging from 50% to 93% and specificities approaching 100%.22,23

In the supine patient, normal lower extremity venous flow is phasic (Fig. 24-5), decreasing with inspiration in response to increased intra-abdominal pressure with the descent of the diaphragm and then increasing with expiration as the diaphragm rises and intra-abdominal pressure decreases. When the patient is upright, the decrease in intra-abdominal pressure with expiration cannot overcome the hydrostatic column of pressure existing between the right atrium and the calf. Muscular contractions of the calf, along with the one-way venous valves, are then required to promote venous return to the heart. Flow also can be increased by leg elevation or compression and decreased by sudden elevation of intra-abdominal pressure (Valsalva maneuver). In a venous DUS examination performed with the patient supine, spontaneous flow, variation of flow with respiration, and response of flow to Valsalva maneuver are all assessed.
Impedance Plethysmography Impedance plethysmography (IPG) was the primary noninvasive method of diagnosing DVT before the widespread use of DUS but is infrequently used today. Changes in electrical resistance resulting from lower extremity blood volume changes are quantified. IPG is less accurate than DUS for the detection of proximal DVT, with 83% sensitivity in symptomatic patients. It is a poor detector of calf vein DVT.

Iodine-125 Fibrinogen Uptake Iodine-125 fibrinogen uptake (FUT) is a seldom used technique that involves IV administration of radioactive fibrinogen and monitoring for increased uptake in fibrin clots. An increase of 20% or more in one area of a limb indicates an area of thrombus. FUT can detect DVT in the calf, but high background radiation from the pelvis and the urinary tract limits its ability to detect proximal DVT. It also cannot be used in an extremity that has recently undergone surgery or has active inflammation. In a prospective study, FUT had a sensitivity of 73% and specificity of 71% for identification of DVT in a group of symptomatic and asymptomatic patients. Currently, FUT is primarily a research tool of historic interest.

Venography Venography is the gold standard to which other diagnostic modalities are compared. A small catheter is placed in a dorsal foot vein with injection of a radiopaque contrast agent. Radiographs are obtained in at least two projections. A positive study result is failure to fill the deep system with passage of the contrast medium into the superficial system or demonstration of discrete filling defects (Fig. 24-8). A normal study result virtually excludes the presence of DVT. In a study of 160 patients with a normal venogram followed for 3 months, only two patients (1.3%) subsequently developed DVT and no patients experienced symptoms of PE.

Venography is not routinely used in clinical practice due to invasiveness and complication risk. It is still, however, frequently used in research studies evaluating DVT prophylaxis.

Treatment Once the diagnosis of VTE has been made, antithrombotic therapy should be initiated promptly. If clinical suspicion for VTE is high, it may be prudent to start treatment while the diagnosis is objectively confirmed. The goals of VTE treatment are the prevention of mortality and morbidity associated with PE and the prevention of the postthrombotic syndrome (PTS). Treatment regimens may include antithrombotic therapy, temporary or permanent vena cava filter placement, catheter-directed or systemic thrombolytic therapy, and operative thrombectomy.

Antithrombotic Therapy. Most often, antithrombotic therapy for VTE is initiated with IV or subcutaneous (SC) unfractionated heparin or SC low molecular weight heparin. Fondaparinux, a synthetic pentasaccharide, is sometimes also used as an alternative to heparin to initiate therapy. An oral vitamin K antagonist, usually sodium warfarin, is begun shortly after initiation of IV or SC therapy. Either SC or IV therapy is continued until effective oral anticoagulation with warfarin is achieved as indicated by an international normalized ratio (INR) ≥2 for 24 hours. A minimum of 5 days of heparin or fondaparinux therapy is recommended. Recently, the U.S. Food and Drug Administration (FDA) has also approved alternative oral anticoagulants for both treatment and prophylaxis for VTE.

Unfractionated heparin (UFH) binds to antithrombin via a specific 18-saccharide sequence. This increases antithrombin activity over 1000-fold. The antithrombin-heparin complex primarily inhibits factor IIa (thrombin) and factor Xa and, to a lesser degree, factors IXa, Xla, and XIIa of the coagulation cascade. In addition, UFH also binds to tissue factor pathway inhibitor, which inhibits the conversion of factor X to Xa, and factor IX to IXa. Finally, UFH catalyzes the inhibition of thrombin by heparin cofactor II via a mechanism independent of antithrombin.

UFH therapy is most commonly administered with an initial IV bolus of 80 units/kg. Weight-based UFH dosages have been shown to be more effective than standard fixed boluses in rapidly achieving therapeutic levels. The initial bolus is followed by a continuous IV drip at 18 units/kg per hour. The half-life of IV UFH ranges from 45 to 90 minutes and is dose dependent. The level of antithrombotic therapy should be monitored every 6 hours using the activated partial thromboplastin time (aPTT), with the goal range of 1.5 to 2.5 times control values. This should correspond with plasma heparin anti-Xa activity levels of 0.3 to 0.7 IU/mL.

Initial anticoagulation with UFH may also be administered SC, although this route is less commonly used. Adjusted-dose therapeutic SC UFH is initiated with 17,500 units, followed by 250 units/kg twice daily, and dosing is adjusted to an aPTT goal range similar to that for IV UFH. Fixed-dose unmonitored SC UFH is started with a bolus of 333 units/kg, followed by 250 units/kg twice daily.

Hemorrhage is the primary complication of UFH therapy. The rate of major hemorrhage (fatal, intracranial, retroperitoneal, or requiring transfusion of >2 units of packed red
blood cells) is approximately 5% in hospitalized patients undergoing UFH therapy (1% in medical patients and 8% in surgical patients). For patients with UFH-related bleeding complications, cessation of UFH is required, and anticoagulation may be reversed with protamine sulfate. Protamine sulfate binds to UFH and forms an inactive salt compound. Each milligram of protamine neutralizes 90 to 115 units of heparin, and the dosage should not exceed 50 mg IV over any 10-minute period. Side effects of protamine sulfate include hypotension, pulmonary edema, and anaphylaxis. Patients with prior exposure to protamine-containing insulin (NPH) and patients with allergy to fish may have an increased risk of hypersensitivity, although no direct relationship has been established. Protamine administration should be terminated if any side effects occur.

In addition to hemorrhage, heparin also has unique complications. Heparin-induced thrombocytopenia (HIT) results from heparin-associated antiplatelet antibodies (HAAbS) directed against platelet factor 4 complexed with heparin. HIT occurs in 1% to 5% of patients being treated with heparin. In patients with repeat heparin exposure (such as vascular surgery patients), the incidence of HAAbS may be as high as 21%. HIT occurs most frequently in the second week of therapy and may lead to disastrous venous or arterial thrombotic complications. Therefore, platelet counts should be monitored periodically in patients receiving continuous heparin therapy.

HIT is diagnosed based on previous exposure to heparin, platelet count less than 100,000, and/or platelet count decline of 50% following exposure. All heparin must be stopped and alternative anticoagulation initiated immediately to avoid thrombotic complications, which may approach 50% over the subsequent 30 days in affected individuals.

Another complication of prolonged high-dose heparin therapy is osteopenia. Heparin-induced osteopenia results from impairment of bone formation and enhancement of bone resorption by heparin.

Low molecular weight heparins (LMWHs) are derived from the depolymerization of porcine UFH. Like UFH, LMWHs bind to antithrombin via a specific pentasaccharide sequence to expose an active site for the neutralization of factor Xa. However, LMWHs have fewer additional saccharide units. This results in less inactivation of thrombin (factor IIa). In comparison to UFH, LMWHs have increased bioavailability (>90% after SC injection), longer half-lives (approximately 4 to 6 hours), and more predictable elimination rates.

Most patients treated with weight-based once- or twice-daily SC LMWH injections do not require laboratory monitoring for anticoagulant effect, a distinct advantage over continuous IV infusions of UFH. Patients who do require monitoring include those with significant renal insufficiency, pediatric patients, obese patients greater than 120 kg, and pregnant patients. Monitoring may be performed using anti-Xa activity assays. The therapeutic anti-Xa goal range depends on the type of LMWH and the frequency of dosing. There are numerous LMWHs available, and the various preparations differ in their anti-Xa and anti-IIa activities. Treatment dosing for one LMWH therefore cannot be extrapolated for use with another. The anticoagulant effect of LMWHs may be partially reversed (approximately 60%) with protamine sulfate.

Numerous well-designed trials comparing SC LMWH with IV and SC UFH for the treatment of DVT have been critically evaluated in several meta-analyses and demonstrate a decrease in thrombotic complications, bleeding, and mortality with LMWHs. LMWHs also are associated with a decreased rate of HAAb formation and HIT (<2%) compared with UFH (at least in prophylactic doses). However, patients with established HIT also should not receive LMWHs because there is cross-reactivity between the drugs.

A major benefit of LMWHs is that it allows outpatient treatment of VTE. In a randomized study comparing IV UFH and the LMWH nadroparin calcium, there was no significant difference in recurrent thromboembolism (6.6% for UFH vs. 6.9% for LMWH) or major bleeding complications (2.0% for UFH vs. 0.5% for LMWH). There was, however, a 67% reduction in mean days in the hospital for the LMWH group.

Fondaparinux currently is a synthetic pentasaccharide that has been approved by the FDA for the initial treatment of DVT and PE. Its five-polysaccharide sequence binds and activates antithrombin, causing specific inhibition of factor Xa. In two large noninferiority trials, fondaparinux was compared with the LMWH enoxaparin for the initial treatment of DVT and with IV UFH for the initial treatment of PE. The rates of recurrent VTE ranged from 3.8% to 5%, with rates of major bleeding of 2% to 2.6%, for all treatment arms. The drug is administered SC once daily with a weight-based dosing protocol: 5 mg, 7.5 mg, or 10 mg for patients weighing <50 kg, 50 to 100 kg, or >100 kg, respectively. The half-life of fondaparinux is approximately 17 hours in patients with normal renal function. There are rare case reports of fondaparinux-induced thrombocytopenia.

Direct thrombin inhibitors (DTIs) include recombinant hirudin, argatroban, and bivalirudin. These antithrombotic agents bind to thrombin, inhibiting the conversion of fibrinogen to fibrin as well as thrombin-induced platelet activation. These actions are independent of antithrombin. The DTIs should be reserved for (a) patients in whom there is a high clinical suspicion or confirmation of HIT, and (b) patients who have a history of HIT or test positive for heparin-associated antibodies. In patients with established HIT, DTIs should be administered for at least 7 days, or until the platelet count normalizes. Warfarin may then be introduced slowly, overlapping therapy with a DTI for at least 5 days.

Bivalirudin is approved primarily for patients with or without HIT who undergo percutaneous coronary intervention and is rarely used outside of that setting.

Commercially available hirudin is manufactured using recombinant DNA technology. It is indicated for the prophylaxis and treatment of patients with HIT. In patients with normal renal function, recombinant hirudin is administered as an IV bolus dose of 0.4 mg/kg, followed by a continuous IV infusion of 0.15 mg/kg per hour. The half-life ranges from 30 to 60 minutes. The aPTT is monitored, starting approximately 4 hours after initiation of therapy, and dosage is adjusted to maintain an aPTT of 1.5 to 2.5 times the laboratory normal value. The less commonly used ecarin clotting time is an alternative method of monitoring. Recombinant hirudin is eliminated via renal excretion, so dosage adjustments are required in patients with renal insufficiency.

Argatroban is indicated for the prophylaxis and treatment of thrombosis in HIT. It also is approved for patients with, or at risk for, HIT undergoing percutaneous coronary intervention. Antithrombotic prophylaxis and therapy are initiated with a continuous IV infusion of 2 μg/kg per minute, without the need for a bolus. The half-life ranges from 39 to 51 minutes, and the dosage is adjusted to maintain an aPTT of 1.5 to 3 times normal. Large initial boluses and higher rates of continuous infusion
are reserved for patients with coronary artery thrombosis and myocardial infarction. In these patients, therapy is monitored using the activated clotting time. Argatroban is metabolized and excreted by the liver; therefore, dosage adjustments are needed in patients with hepatic impairment. There is no reversal agent for argatroban.

**Vitamin K antagonists**, which include warfarin and other coumarin derivatives, are the mainstay of long-term antithrombotic therapy in patients with VTE. Warfarin inhibits the γ-carboxylation of vitamin K–dependent coagulants (factors II, VII, IX, and X) and anticoagulants (proteins C and S), resulting in formation of less functional proteins. Warfarin usually requires several days to achieve full effect because normal circulating coagulation proteins must first undergo their normal degradation. Factors X and II have the longest half-lives, in the range of 36 and 72 hours, respectively. A steady-state concentration of warfarin is usually not reached for 4 to 5 days.

Warfarin therapy is monitored by measuring the INR, calculated using the following equation:

\[
\text{INR} = \left( \frac{\text{patient prothrombin time}}{\text{laboratory normal prothrombin time}} \right)^{ISI}
\]

where *ISI* is the international sensitivity index. The ISI describes the strength of the thromboplastin that is added to activate the extrinsic coagulation pathway. The therapeutic target INR range is usually 2.0 to 3.0, but the response to warfarin is variable and depends on liver function, diet, age, and concomitant medications. In patients receiving anticoagulation therapy without concomitant thrombolysis or venous thrombectomy, the vitamin K antagonist may be started on the same day as the initial parenteral anticoagulant, usually at doses ranging from 5 to 10 mg. Smaller initial doses may be needed in older and malnourished patients, in those with liver disease or congestive heart failure, and in those who have recently undergone major surgery.45

The recommended duration of warfarin antithrombotic therapy is stratified based on whether the DVT was provoked or unprovoked, whether it was the first or a recurrent episode, where the DVT is located, and whether malignancy or thrombophilia is present. Current ACCP recommendations for duration of warfarin therapy are summarized in Table 24-4.

In patients with proximal DVT, several randomized clinical trials have demonstrated that shorter-term antithrombotic therapy (4 to 6 weeks) is associated with a higher rate of VTE recurrence than 3 to 6 months of anticoagulation.46-48 In these trials, most of the patients with transient risk factors had a low rate of recurrent VTE, and most recurrences were in patients with continuing risk factors. The ACCP recommendation, therefore, is that 3 months of anticoagulation are sufficient to prevent recurrent VTE in patients with DVT occurring around the time of a transient risk factor (e.g., hospitalization, orthopedic or major general surgery).

In contrast to patients with thrombosis related to transient risk factors, patients with idiopathic VTE are much more likely to develop recurrence (rates as high as 40% at 10 years). In this latter group of patients, numerous clinical trials have compared 3 to 6 months of anticoagulation therapy with extended-duration warfarin therapy, both at low intensity (INR of 1.5 to 2.0) and at conventional intensity (INR of 2.0 to 3.0).49-51 In patients with idiopathic DVT, extended-duration antithrombotic therapy is associated with a relative reduction in the rate of recurrent VTE by 75% to >90%. In addition, conventional-intensity warfarin reduces the risk even further compared with low-intensity warfarin (0.7 events per 100 person-years vs. 1.9 events per 100 person-years) without an increase in bleeding complications.52

In patients with VTE in association with a hypercoagulable condition, the optimal duration of anticoagulation therapy is influenced more by the clinical circumstances at the time of the VTE (idiopathic vs. secondary) than by the actual presence or absence of the more common thrombophilic conditions. In patients with VTE related to malignancy, increasing evidence suggests that longer-term therapy with LMWH (up to 6 months) is associated with a lower VTE recurrence than treatment using conventional vitamin K antagonists.53,54 The primary complication of warfarin therapy is hemorrhage, and the risk is related to the magnitude of INR prolongation. Depending on the INR and the presence of bleeding, warfarin anticoagulation may be reversed by (a) omitting or decreasing subsequent dosages, (b) administering oral or parenteral vitamin K, or (c) administering fresh-frozen plasma, prothrombin complex concentrate, or recombinant factor VIIa.45

Warfarin therapy rarely may be associated with the development of skin necrosis and limb gangrene. These conditions occur more commonly in women (4:1), and the most commonly affected areas are the breast, buttocks, and thighs. This complication, which usually occurs in the first days of therapy, is occasionally, but not exclusively, associated with protein C or S deficiency and malignancy. Patients who require continued anticoagulation may restart low-dose warfarin (2 mg) while receiving

concomitant therapeutic heparin. The warfarin dosage is then gradually increased over a 1- to 2-week period.45

**Systemic and Catheter-Directed Thrombolysis.** Patients with extensive proximal, iliofemoral DVT may benefit from systemic thrombolysis or catheter-directed thrombolysis (CDT). CDT appears to be more effective (see later in chapter) and potentially reduces acute congestive lower extremity symptoms more rapidly than anticoagulation alone and decreases the development of PTS.

Several thrombolytic agents are available, including streptokinase, urokinase, alteplase (recombinant tissue plasminogen activator), retelase, and tenecteplase. All share the ability to convert plasminogen to plasmin, which leads to the degradation of fibrin. They differ with regard to their half-lives, their potential for inducing fibrinogenolysis (generalized lytic state), their potential for antigenicity, and their FDA-approved indications for use.

Streptokinase is purified from β-hemolytic Streptococcus and is approved for the treatment of acute myocardial infarction, PE, DVT, arterial thromboembolism, and occluded central lines and arteriovenous shunts. It is not specific for fibrin-bound plasminogen, however, and its use is limited by its significant rates of antigenicity. Fevers and shivering occur in 1% to 4% of patients.

Urokinase is derived from human neonatal kidney cells grown in tissue culture. Currently, it is only approved for lysis of massive PE or PE associated with unstable hemodynamics.

Alteplase, retelase, and tenecteplase all are recombinant variants of tissue plasminogen activator. Alteplase is indicated for the treatment of acute myocardial infarction, acute ischemic stroke, and acute massive PE. However, it often is used for CDT of DVT. Retelase and tenecteplase are indicated only for the treatment of acute myocardial infarction.

Systemic thrombolysis was evaluated in numerous older prospective and randomized clinical trials, and its efficacy was summarized in a recent Cochrane Review.50 In 12 studies involving over 700 patients, systemic thrombolysis was associated with significantly more clot lysis (relative risk [RR] 0.24 to 0.37) and significantly less PTS (RR 0.66). However, venous function was not significantly improved. In addition, more bleeding complications occurred (RR 1.73).

In an effort to minimize bleeding complications and increase efficacy, CDT techniques were developed for the treatment of symptomatic primarily iliofemoral DVT. With catheter-directed therapy, venous access may be achieved through percutaneous catheterization of the ipsilateral popliteal vein, retrograde catheterization through the contralateral femoral vein, or retrograde cannulation from the internal jugular vein. Multi-side-hole infusion catheters, with or without infusion wires, are used to deliver the lytic agent directly into the thrombus. Lytic agents may be administered alone or, more commonly, in combination with catheter-based methods to physically break up the clot—so-called pharmacomechanical thrombolysis.

The efficacy of CDT for the treatment of symptomatic iliofemoral DVT has been reported in a large multicenter randomized control trial. Two-hundred and nine patients with proximal DVT were assigned to conventional anticoagulant therapy versus conventional anticoagulant therapy plus CDT. In the CDT group, placement of a venous stent was permitted for any identified iliac vein stenotic lesion. At 6 months, iliac vein patency was significantly improved in the thrombolysis group (65.9% vs. 47.4%). At 2 years, in the CDT group, there was an absolute risk reduction of nearly 15% for development of PTS, translating to a number needed to treat of seven patients to prevent one case of PTS.56

**Inferior Vena Caval Filters.** Since the introduction of the Kimray-Greenfield filter in the United States in 1973, numerous vena caval filters have been developed. Although the designs are variable, they all prevent pulmonary emboli, while allowing continuation of venous blood flow through the IVC. Early filters were placed surgically through the femoral vein. Currently, less invasive techniques allow percutaneous filter placement through a femoral vein, internal jugular vein, or small peripheral vein under fluoroscopic or ultrasound guidance.

Placement of an IVC filter is indicated for patients who have manifestations of lower extremity VTE and absolute contraindications to anticoagulation, those that have a bleeding complication from anticoagulation therapy of acute VTE, or those who develop recurrent DVT or PE despite adequate anticoagulation therapy and for patients with severe pulmonary hypertension.

When possible, therapy should be continued in patients with vena cava filters. The duration of anticoagulation is determined by the underlying VTE and not by the presence of the IVC filter itself. Practically speaking, however, many patients who require an IVC filter for recurrent VTE are the same ones who would benefit most from indefinite anticoagulation. In patients who are not able to receive anticoagulants due to recent surgery or trauma, the clinician should continually reassess if anticoagulation may be started safely at a later date.

Placement of permanent IVC filters has been evaluated as an adjunct to routine anticoagulation in patients with proximal DVT.54 Routine IVC filter placement has not been shown to prolong early or late survival in patients with proximal DVT but did decrease the rate of PE (hazard ratio, 0.22; 95% confidence interval, 0.05–0.90), however; an increased rate of recurrent DVT was seen in patients with IVC filters (hazard ratio, 1.87; 95% confidence interval, 1.10–3.20).

IVC filters are associated with acute and late complications. Acute complications include thrombosis or bleeding at the insertion site and misplacement of the filter. Late complications include thrombosis of the IVC, DVT, breaking, migration, or erosion of the filter through the IVC (Fig. 24-9). The rate of fatal complications is <0.12%.54

In some patients, the need for an IVC filter may be self-limited. Such patients can be treated with so-called removable IVC filters. Depending on the device, removable IVC filters are potentially removable by percutaneous endovascular techniques for up to several months after their initial implantation assuming the filter is no longer required and does not have large amounts of trapped thrombi. All temporary IVC filters are approved for permanent implantation, and many so-called temporary filters end up as permanent devices with all the potential complications of permanent IVC filters.

**Operative Venous Thrombectomy.** In patients with acute iliofemoral DVT, surgical therapy is generally reserved for patients who worsen with anticoagulation therapy and those with phlegmasia cerulea dolens and impending venous gangrene. If the patient has phlegmasia cerulea dolens, a fasciotomy of the calf compartments is first performed. In iliofemoral DVT, a longitudinal venotomy is made in the common femoral vein and a venous balloon embolectomy catheter is passed through
the thrombus into the IVC and pulled back several times until no further thrombus can be extracted. The distal thrombus in the leg is removed by manual pressure beginning in the foot. This is accomplished by application of a tight rubber elastic wrap beginning at the foot and extending to the thigh. If the thrombus in the femoral vein is old and cannot be extracted, the vein may be ligated. For a thrombus that extends into the IVC, the IVC is exposed transperitoneally and controlled below the renal veins. The IVC is opened and the thrombus is removed by gentle massage. An intraoperative completion venogram determines if any residual thrombus or stenosis is present. If a residual iliac vein stenosis is present, intraoperative angioplasty and stenting can be performed. In most cases, an arteriovenous fistula is then created by anastomosing the great saphenous vein (GSV) end to side with the superficial femoral artery in an effort to maintain patency of the thrombectomized iliopoplural venous segment. Heparin is administered postoperatively for several days. Warfarin anticoagulation is maintained for at least 6 months after thrombectomy. Complications of iliopoplural thrombectomy include PE in up to 20% of patients and death in <1% of patients.

One study followed 77 limbs for a mean of 8.5 years after thrombectomy for acute iliopoplural DVT. In limbs with successful thrombectomy, valvular competence in the thrombectomized venous segment was 80% at 5 years and 56% at 10 years. More than 90% of patients had minimal or no symptoms of PTS. There were 12 (16%) early thrombectomy failures. Patients were required to wear compression stockings for at least 1 year after thrombectomy.

Survival rates for surgical pulmonary embolectomy have improved over the past 20 years with the addition of cardiopulmonary bypass. Emergency pulmonary embolectomy for acute PE is rarely indicated. Patients with preterminal massive PE (Fig. 24-10) for whom thrombolysis has failed or who have contraindications to thrombolytics may be candidates for this procedure. Open pulmonary artery embolectomy is performed through a posterolateral thoracotomy with direct visualization of the pulmonary arteries. Mortality rates range between 20% and 40%.

Percutaneous catheter-based techniques for removal of a PE involve mechanical thrombus fragmentation or embolectomy using suction devices. Mechanical clot fragmentation is followed by CDT. Results of catheter-based fragmentation are based on small case series. In a study in which a fragmentation device was used in 10 patients with acute massive PE, fragmentation was successful in 7 patients with a mortality rate of 20%. Transvenous catheter pulmonary suction embolectomy has also been performed for acute massive PE with a reported 76% successful extraction rate and a 30-day survival of 70%.

Prophylaxis

Patients who undergo major general surgical, gynecologic, urologic, and neurosurgical procedures without thromboprophylaxis have a significant incidence of perioperative DVT. An estimated one third of the 150,000 to 200,000 VTE-related deaths per year in the United States occur following surgery. The goal of prophylaxis is to reduce the mortality and morbidity associated with VTE. The first manifestation of VTE may be a life-threatening PE (Fig. 24-11), and as indicated earlier, clinical evaluation to detect DVT before PE is unreliable.

Effective methods of VTE prophylaxis involve the use of one or more pharmacologic or mechanical modalities. Currently available pharmacologic agents include low-dose UFH, LMWH, synthetic pentasaccharides, and vitamin K antagonists. Mechanical methods include intermittent pneumatic compression (IPC) and graduated compression stockings.
There is insufficient evidence to consider aspirin alone as adequate DVT prophylaxis. Methods of prophylaxis vary with regard to efficacy, and the 2012 ACCP Clinical Practice Guidelines stratify their uses according to the patient’s level of VTE risk, bleeding risk, and the values and preferences of individual patients (see Table 24-3).

**Venous Thromboembolism Prophylaxis in Nonorthopedic Surgery.** The risk for VTE associated with a surgical procedure depends on the type of operation, type of anesthesia, duration of surgery, and other risk factors, such as patient age, presence of cancer, prior VTE, obesity, presence of infection, and known thrombophilic disorders. VTE risk can be stratified according to the previously mentioned risk assessment models, the Caprini score and Rogers score. These risk assessment models are included in the prophylaxis guidelines for nonorthopedic surgery (Tables 24-5 and 24-6). A composite score is created using assigned values for each risk factor. The cumulative score for each patient is then used to predict thrombosis risk and provide recommendations regarding VTE prophylaxis.

Patients at very low risk (<0.5%; Rogers score <7; Caprini score 0) who undergo general or abdominopelvic procedures do not require pharmacologic or mechanical prophylaxis; however, early ambulation is required. Patients at low risk (<1.5%; Rogers score 7–10; Caprini score 1–2) should receive mechanical prophylaxis. Patients at moderate risk (3%; Rogers score >10; Caprini score 3–4) should receive LMWH at recommended doses, low-dose UFH, or mechanical prophylaxis. Patients at high risk (6%; Caprini score ≥5) should receive LMWH at recommended doses or low-dose UFH and mechanical prophylaxis. Thromboprophylaxis should continue until discharge, except in select high-risk patients with malignancy in whom extended-duration prophylaxis (up to 4–6 weeks) may be beneficial. Patients with significant risk for bleeding should receive mechanical prophylaxis until this risk subsides.67

Overall, low-dose UFH and LMWH reduce the risk for symptomatic and asymptomatic VTE by 60% to 70%. The risks for bleeding differ, depending on the dosage. Lower dosages of LMWH appear to be associated with less bleeding risk than low-dose UFH, but the latter produces less bleeding risk than higher prophylactic dosages of LMWH.68 Other advantages of LMWH include once-daily dosing protocols and a lower rate of heparin-associated antibody formation.

Fondaparinux has been compared with the LMWH dalteparin in patients who undergo high-risk major abdominal surgery. It also has been compared with IPC alone in patients undergoing non–high-risk abdominal surgery.39–40 Fondaparinux demonstrated rates of VTE prevention, bleeding complications, and mortality similar to those of LMWH. It was more beneficial than IPC alone in reducing VTE but with a higher rate of bleeding (1.6% vs. 0.2%).

Prophylactic insertion of IVC filters has been suggested for VTE prophylaxis in high-risk trauma patients, bariatric surgical patients, and some patients with malignancy who have contraindications for LMWH therapy.41 A 5-year study of prophylactic IVC filter placement in 132 trauma patients at high risk of PE (head injury, spinal cord injury, pelvic or long bone fractures) reported a 0% incidence of symptomatic PE in patients with a correctly positioned IVC filter.42 In 47 patients with a malpositioned IVC filter (strut malposition or filter tilt), there was a 6.3% incidence of symptomatic PE with three deaths. DVT occurred at the insertion site in 3.1% of the patients. IVC patency was 97.1% at 3 years.

Fatal and nonfatal PE can still occur in patients with vena cava interruption. As noted earlier, long-term complications associated with permanent IVC filters include IVC thrombosis and DVT. Currently, the ACCP recommends IVC filters be placed only if a proximal DVT is present and anticoagulation therapy is contraindicated. IVC filter insertion is not recommended for primary prophylaxis.40

Removable IVC filters may be placed in patients with a temporarily increased risk of PE.43 The best patient groups for retrievable filter placement may include young trauma patients with transient immobility, patients undergoing surgical procedures associated with a high risk of PE, and patients with hypercoagulable states who cannot receive anticoagulation therapy for a short period of time. Careful follow-up is required to assure all potentially removable filters are in fact removed.

OTHER VENOUS THROMBOTIC DISORDERS

Superficial Vein Thrombophlebitis
Superficial vein thrombophlebitis (SVT) most commonly occurs in varicose veins but can occur in normal veins. When SVT recurs at variable sites in normal superficial veins, thrombophlebitis migrans, it may signify a hidden visceral malignancy or a systemic disorder such as a blood dyscrasia and/or a collagen vascular disease. SVT also frequently occurs as a complication of indwelling catheters, with or without associated extravasation of injected material. Upper extremity vein

BMI = body mass index; VTE = venous thromboembolism.

thrombosis has been reported to occur in 38% of patients with peripherally inserted central catheters; 57% of these developed in the cephalic vein (Fig. 24-12). Suppurative SVT may occur in veins with indwelling catheters and may be associated with generalized sepsis.

Clinical signs of SVT include redness, warmth, and tenderness along the distribution of the affected veins, often associated with a palpable cord. Patients with suppurative SVT may have fever and leukocytosis. DUS should be performed in patients with signs and symptoms of acute SVT to confirm the diagnosis and to determine if any associated DVT is present. Concomitant lower extremity DVT may be present in 5% to 40% of patients with SVT; most occur in patients with greater saphenous vein SVT within 1 cm of the saphenofemoral junction. A follow-up DUS should be performed in 5 to 7 days in patients with SVT in the proximal GSV but without deep vein involvement. Approximately 10% to 20% of patients with SVT involving the proximal GSV experience progression to deep venous involvement within 1 week.

Treatment of SVT is quite variable. A Cochrane Review reported that LMWHs and nonsteroidal anti-inflammatory drugs both reduce the rate of SVT extension or recurrence. Topical medications appear to improve local symptoms. Surgical treatment, combined with the use of graduated compression stockings, is associated with a lower rate of VTE and SVT progression. The treatment is individualized and depends on the location of the thrombus and the severity of symptoms. In patients with SVT not within 1 cm of the saphenofemoral junction, treatment consists of compression and administration of an anti-inflammatory medication such as indomethacin. In patients with suppurative SVT, antibiotics and removal of any existing indwelling catheters are mandatory. Excision of the vein may be necessary but is usually reserved for patients with systemic symptoms or when excision of the involved vein is straightforward. If the SVT extends proximally to within 1 cm of the saphenofemoral junction, extension into the common femoral vein is more likely to occur. In these patients, anticoagulation therapy for 6 weeks and GSV ligation appear equally effective in preventing thrombus extension into the deep venous system.

Upper Extremity Vein Thrombosis

Axillary-subclavian venous thrombosis (ASVT) is classified into two forms. Primary ASVT occurs in only a small minority of all patients with ASVT. In the primary form, no clear cause for the thrombosis is readily identifiable at initial evaluation. Patients with primary ASVT often give a history of performing prolonged, repetitive motion activities, which results in damage to the subclavian vein, usually where it passes between the head of the clavicle and the first rib in association with the subclavius muscle. This condition is also known as venous thoracic outlet syndrome, effort thrombosis, and Paget-Schroetter syndrome. Secondary ASVT is more common and is associated with an easily identified cause such as an indwelling catheter or a hypercoagulable state. Over 30% of patients with tunneled subclavian vein access devices develop ASVT.

A patient with ASVT may be asymptomatic or may present with varying degrees of upper extremity edema, tenderness, and conspicuous superficial venous enlargement. DUS can be performed initially to confirm the diagnosis, but limitations to the exam by the clavicle and collateralization can lead to a false-negative study. Venography is recommended when there is nonconcordance between the duplex study and clinical suspicion. Anticoagulation therapy should be initiated once ASVT is diagnosed to prevent PE and decrease symptoms.

Treatment of patients with primary upper extremity venous thrombosis is controversial because the natural history of the disease may vary from minimal to no symptoms to significant symptoms with vigorous upper extremity activities. In recent years, patients presenting with acute symptomatic primary ASVT are often considered candidates for CDT therapy with the goal of minimizing long-term symptoms of venous congestion. Venography is performed through a catheter placed using an ultrasound-guided percutaneous basilic vein approach to document the extent of the thrombus (Fig. 24-13). A guidewire is traversed through the thrombus, and a catheter is placed within the thrombus. Typically, tissue plasminogen activator is administered through a multi–side-hole infusion catheter. Various catheter-based mechanical techniques may also be employed to speed thrombus removal. Heparin is administered concurrently with the thrombolytic infusion.
of thrombolytic therapy, a follow-up venogram is obtained. Correctable anatomic abnormalities may then be considered for treatment. Adjuvant procedures after thrombolytic therapy may include cervical or first rib resection for thoracic outlet abnormalities, surgical venous reconstruction, and balloon angioplasty of residual venous stenosis.\textsuperscript{61}

Mesenteric Vein Thrombosis

Five to 15\% of cases of acute mesenteric ischemia occur as a result of mesenteric vein thrombosis (MVT). Mortality rates in patients with MVT may approach 50\%.\textsuperscript{62} The usual presenting symptom is nonspecific abdominal pain and distention, often accompanied by nausea, vomiting, and diarrhea.\textsuperscript{63} Peritoneal signs, suggesting intestinal infarction, are present in fewer than half of MVT patients. MVT is more common in patients with a hypercoagulable state, malignancy, and cirrhosis. MVT occurs as a rare complication of laparoscopic surgery.\textsuperscript{83,84}

Most cases of MVT are diagnosed with contrast-enhanced CT scanning or magnetic resonance imaging (MRI) in the course of an evaluation for abdominal pain. The sensitivity and specificity for CT and MRI approach 100\% and 98\%, respectively.\textsuperscript{63} Ultrasound can also be used and has reported sensitivity and specificity of 93\% and 99\%, respectively.

Patients with MVT are treated with fluid resuscitation, heparin anticoagulation, and bowel rest. Once the patient’s clinical status improves, oral intake can be carefully started. The patient is transitioned to oral anticoagulation over 3 to 4 days and, depending on the etiology of the MVT, continued for 3 to 6 months or indefinitely. Most patients with MVT can be treated nonoperatively, but urgent laparotomy is indicated in patients with peritoneal findings. Broad-spectrum antibiotics are administered perioperatively. Operative findings consist of edema and cyanotic discoloration of the mesentery and bowel wall. In more advanced cases, thrombus involves the distal mesenteric veins. The arterial supply to the involved bowel is usually intact. Nonviable bowel is resected, and primary anastomosis can be performed. If the viability of the remaining bowel is in question, a second-look operation is performed within 24 to 48 hours.

VARICOSE VEINS

Varicose veins are common and are present in at least 10\% of the general population.\textsuperscript{65} The findings of varicose veins may include dilated and tortuous veins, telangiectasias, and fine reticular varicosities. Risk factors for varicose veins include obesity, female sex, inactivity, and family history.\textsuperscript{67} Varicose veins can be classified as primary or secondary. Primary varicose veins result from intrinsic abnormalities of the venous wall, whereas secondary varicose veins are associated with deep and/ or superficial venous insufficiency.

Patients with varicose veins may complain of unsightly appearance, aching, heaviness, pruritus, and early fatigue of the affected leg. These symptoms worsen with prolonged standing and sitting and are relieved by elevation of the leg above the level of the heart. A mild amount of edema is often present. More severe signs include thrombophlebitis, hyperpigmentation, lipodermatosclerosis, ulceration, and bleeding from attenuated vein clusters.

An important component of treatment for patients with varicose veins is the use of elastic compression stockings. Patients may be prescribed elastic stockings with compression ranging from 20 to 30, 30 to 40, or even 40 to 50 mmHg. Stocks range in length from knee high to waist high, and they should cover the symptomatic varices. Elastic compression provides sufficient relief of symptoms in many symptomatic patients.

Cosmetic concerns may lead to intervention. Additionally, interventions are warranted in patients whose symptoms worsen or are unrelieved despite compression therapy or who have lipodermatosclerosis or venous ulcer. Randomized trials of symptomatic patients with varicose veins have demonstrated improved quality of life with interventional treatment. Interventional management includes injection sclerotherapy, surgical therapy, or a combination of both techniques. Injection sclerotherapy alone can be successful in varicose veins <3 mm in diameter and in telangiectatic vessels. Sclerotherapy acts by destroying the venous endothelium. Sclerosing agents include hypertonic saline, sodium tetradecyl sulfate, and polidocanol. Concentrations of 11.7\% to 23.4\% hypertonic saline, 0.125\% to 0.250\% sodium tetradecyl sulfate, and 0.5\% polidocanol are used for telangiectasias. Larger varicose veins require higher concentrations: 23.4\% hypertonic saline, 0.50\% to 1\% sodium tetradecyl sulfate, and 0.75\% to 1.0\% polidocanol.\textsuperscript{63} Elastic bandages are wrapped around the leg after injection and worn continuously for 3 to 5 days to produce apposition of the inflamed vein walls and prevent thrombus formation. After the bandages are removed, elastic compression stockings should be worn for a minimum of 2 weeks. Complications from sclerotherapy include allergic reaction, local hyperpigmentation, thrombophlebitis, DVT, and possible skin necrosis.

Patients with symptomatic GSV or SSV reflux may be treated with endovenous ablation techniques or surgical removal of the affected vein. Endovenous laser and radiofrequency ablation (RFA) techniques have gained in popularity in the past several years. Such techniques are generally associated with more rapid postprocedural recovery than traditional open surgical stripping of the GSV.

With either endoluminal technique, the distal thigh or proximal calf GSV is punctured with a 21-gauge needle under ultrasound guidance. A sheath is placed over a guidewire, and the laser fiber or RFA catheter is advanced until it is near to, but not at, the saphenofemoral junction. Tumescent anesthetic provides sufficient relief of symptoms in many symptom
The annual healthcare cost in the United States for CVIs is staggering, with an estimated 2 million workdays lost per year. 

Chronic venous insufficiency (CVI) affects an estimated 600,000 people in the United States. Patients complain of leg fatigue, discomfort, and heaviness. Signs of CVI may include varicose veins, pigmentation, lipodermatosclerosis, and venous ulceration. Importantly, severe CVI is not necessarily associated with varicose veins. Chronic venous ulcers carry significant negative physical, financial, and psychological implications. A quality-of-life study reported that 65% of patients with chronic leg ulcers had severe pain, 81% had decreased mobility, and 100% experienced a negative impact of their disease on their work capacity. The socioeconomic impact of chronic venous leg ulcers is staggering, with an estimated 2 million workdays lost per year. The annual healthcare cost in the United States to treat CVI is estimated at $1 billion.

CVI can be primary or secondary. Primary CVI results from intrinsic abnormalities of the vein wall, whereas secondary CVI, so-called postthrombotic syndrome (PTS), occurs as a result of DVT. The signs and symptoms of CVI can be therefore attributed to venous reflux, venous obstruction, calf muscle pump dysfunction, or a combination of these factors, as well as loss of venous wall elasticity. In the majority of patients with CVI, the most important factor appears to be venous reflux. Venous reflux results from abnormalities of the venous valve. Primary valvular reflux or incompetence is diagnosed when there is no known underlying cause of valvular dysfunction. Secondary valvular reflux is diagnosed when an identifiable cause is present. The most frequent secondary cause is DVT.

Evaluation of Venous Insufficiency

Early diagnostic studies to evaluate CVI required invasive measurements of ambulatory venous pressure (AVP) and venous recovery time (VRT). To measure AVP and VRT, a needle is inserted into a dorsal foot vein and connected to a pressure transducer. The patient is asked to perform 10 tiptoe exercises. Initially there is often a slight upward deflection of pressure with the onset of exercise followed by a decline in pressure with each subsequent tiptoe maneuver. After approximately 10 tiptoes, the measured pressure stabilizes and reflects a balance of venous inflow and outflow. The pressure at this point is the AVP, which is measured in millimeters of mercury. The patient is then asked to stop exercising to allow the vein to fill with return of the venous pressure to baseline. The time required for the venous pressure to return from the AVP level to 90% of baseline pressure is referred to as the VRT. Elevations of AVP indicate venous hypertension. The magnitude of AVP reflects the severity of CVI. There is an 80% incidence of venous ulceration in patients with an AVP of >80 mmHg.

Plethysmography. Noninvasive plethysmography has been used to evaluate CVI. Venous photoplethysmography indirectly evaluates venous function through the use of infrared light. A light-emitting diode is placed just above the medial malleolus, and the patient then performs a series of tiptoe maneuvers. Photoplethysmography provides a measurement of VRT. In limbs with CVI, VRT is shortened compared with that in a normal limb. AVP and VRT are only measures of the overall venous function of a lower extremity venous system. They cannot localize the site of reflux or evaluate the function of the calf pump.

Air plethysmography is a theoretically attractive but not widely used method to assess calf pump function, venous reflux, and overall lower extremity venous function. An air-filled plastic pressure bladder is placed on the calf to detect volume changes in the leg during a standard set of maneuvers. The patient is first supine and then the leg is elevated and the minimum volume of venous blood recorded. The patient is then asked to assume an upright position with the examined leg non-weight bearing. The venous volume of the examined leg is determined when the volume curve flattens. The venous filling index (VFI), a measure of reflux, is calculated by dividing the maximum venous volume by the time required to achieve maximum venous volume. Next, the patient performs a single tiptoe maneuver, and the ejection fraction (EF) is determined. The EF is the volume change between the recorded volume before and after the tiptoe maneuver and is a measure of calf pump function. At this point, the veins of the leg are allowed to refill. The patient then performs 10 tiptoe maneuvers, and the residual volume fraction is calculated by dividing the venous volume in the leg after 10 tiptoe exercises by the venous volume present before the exercises. The residual volume fraction is a reflection of overall venous function. Theoretically, patients with increased VFIs and normal EFs (indicating the presence of reflux with normal calf pump function) would benefit from anti-reflux surgery, whereas patients with normal VFIs and diminished EFs would not.

Venous Duplex Ultrasound. Venous DUS has become the gold standard for evaluation of venous function largely supplanting venographic and plethysmographic techniques. The principle advantage of DUS is that it can be used to evaluate reflux in individual venous segments targeting abnormal areas for treatment. The examination has been validated when performed with the patient in the standing position and the examined leg non-weight bearing. Pneumatic pressure cuffs of appropriate size are placed around the thigh, calf, and forefoot. The ultrasound transducer is positioned over the venous segment to be examined, just proximal to the pneumatic cuff (Fig. 24-15). The cuff is then inflated to a standard pressure for 3 seconds and then rapidly deflated. Ninety-five percent of normal venous valves close within 0.5 second. The presence of reflux for >0.5 second is considered abnormal. Typically, the common femoral, femoral, popliteal, and posterior tibial veins, as well as the GSV and SSV, are evaluated in a complete examination.
therapy. Hypothesized as the mechanisms of efficacy of compression as well as a direct effect on subcutaneous pressure have been in skin and subcutaneous tissue microcirculatory hemodynamics. Therapy can improve CVI remains uncertain. An improvement in skin and subcutaneous tissue. Increases in subcutaneous tissue oxygen and other nutrients to the cellular elements of skin cutaneous metabolism may improve due to enhanced diffusion matrix metalloproteins and inflammatory cytokines. Quantifiable differences in ulcer healing with decreases in edema reduction, perimalleolar subcutaneous pressure has been demonstrated to lower extremity edema in patients with CVI. In addition, supine activity tolerance, depression, and sleep alterations. Patients with edema, such as diabetes mellitus, immunosuppression, malnutrition, and congestive heart failure, should be improved as much as possible.

Compression therapy is most commonly achieved with graduated elastic compression stockings. Elastic compression stockings are available in various compositions, strengths, and lengths, and can be customized for a particular patient. The benefits of elastic compression stocking therapy for the treatment of CVI and healing of ulcers have been well documented. In a retrospective study involving 113 venous ulcer patients, the use of below-knee, 30- to 40-mmHg elastic compression stockings, after edema and cellulitis were first resolved if present, resulted in 93% healing. Complete ulcer healing occurred in 99 of 102 patients (97%) who were compliant with stocking use vs. 6 of 11 patients (55%) who were noncompliant (P < .0001). The mean time to ulcer healing was 5 months. The rate of ulcer recurrence was lower in patients who were compliant with their compression therapy. By life table analysis, ulcer recurrence was 29% at 5 years for compliant patients and 100% at 3 years for noncompliant patients.

In addition to promoting ulcer healing, elastic compression therapy can also improve quality of life in patients with CVI. In one prospective study, 112 patients with CVI documented by DUS were administered a questionnaire to quantify the symptoms of swelling, pain, skin discoloration, cosmesis, activity tolerance, depression, and sleep alterations. Patients were treated with 30- to 40-mmHg elastic compression stockings. There were overall improvements in symptom severity scores at 1 month after initiation of treatment. Further improvements were noted at 16 months after treatment.

Patient compliance with compression therapy is crucial in treating CVI and especially venous leg ulcers. Many patients are initially intolerant of compression in areas of hypersensitivity adjacent to an active ulcer or at sites of previously healed ulcers. They may also have difficulty applying elastic stockings.

To improve compliance, patients should be instructed to wear their stockings initially only as long as it is easily tolerated and then gradually to increase the amount of time the stockings are worn. Alternatively, patients can be fitted with lower-strength stockings initially followed by introduction of higher-strength stockings over a period of several weeks. Many commercially available devices, such as silk inner toe liners, adjustable elastic compression with Velcro, stockings with zippered sides (Fig. 24-17), and metal fitting aids (Fig. 24-18), are available to assist patients in applying elastic stockings. However, despite all these available adjuncts, many patients remain noncompliant with elastic compression therapy.

Another method of compression was developed by the German dermatologist Paul Gerson Unna. Unna’s boot has
been used for many years to treat venous ulcers and is available in many versions. A typical Unna’s boot consists of a three-layer dressing and requires application by trained personnel. A rolled gauze bandage impregnated with calamine, zinc oxide, glycerin, sorbitol, gelatin, and magnesium aluminum silicate is first applied with graded compression from the forefoot to just below the knee. The next layer consists of a 4-in-wide continuous gauze dressing followed by an outer layer of elastic wrap, also applied with graded compression. The bandage becomes stiff after drying, and the rigidity may aid in preventing edema formation. Unna’s boot is changed weekly or sooner if the patient experiences significant drainage and soiling of the dressing.

Once applied, Unna’s boot requires minimal patient involvement and provides continuous compression and topical therapy. However, Unna’s boot has several disadvantages. It is bulky and can be uncomfortable, which may affect patient compliance. In addition, the ulcer cannot be monitored after the boot is applied, the technique is labor intensive, and the degree of compression provided is operator dependent. Occasionally, patients may also develop contact dermatitis to the components of Unna’s boot.

The efficacy of Unna’s dressing has been studied. A retrospective 15-year survey encompassing 998 patients with one or more venous ulcers treated weekly with Unna’s dressing reported that 73% of ulcers healed in patients who returned for more than one treatment. The median time to healing for individual ulcers was 9 weeks. Unna’s dressing has been compared to other forms of treatment. A randomized, prospective study comparing Unna’s boot to polyurethane foam dressing in 36 patients with venous ulcers demonstrated superior healing over 12 months in patients treated with Unna’s boot (94.7% vs. 41.2%). A recent Cochrane Review of 39 randomized controlled trials demonstrated that compression increases ulcer healing rates compared with no compression, multicomponent systems are more effective than single-component systems, and multicomponent systems that include an elastic bandage are more effective than those composed mainly of inelastic constituents.

Other forms of compression dressing available to treat CVI include multilayered dressings and legging orthoses. The purported advantages of multilayered dressings include maintenance of compression for a longer period of time, more even distribution of compression, and better absorption of wound exudates. However, the efficacy of multilayered dressings depends on the wrapping technique of healthcare personnel. A commercially available legging orthosis consisting of multiple adjustable loop-and-hook closure compression bands provides compression similar to that of Unna’s boot and can be applied daily by the patient.

**Skin Substitutes.** Several types of skin substitutes are commercially available or under clinical study in the United States. Bioengineered skin ranges in composition from acellular skin substitutes to partial living skin substitutes. Their mechanism of action in healing venous ulcers is uncertain; however, they may serve as delivery vehicles for various growth factors and cytokines important in wound healing.

Apligraf is a commercially available bilayered living skin construct that closely approximates human skin for use in the treatment of venous ulcers. It contains a protective stratum corneum and a keratinocyte-containing epidermis overlying a dermis consisting of dermal fibroblasts in a collagen matrix.
Apligraf is between 0.5 mm and 1.0 mm thick and is supplied as a disk of living tissue on an agarose gel nutrient medium. It must be used within 5 days of release from the manufacturer.\textsuperscript{11} (Fig. 24-19). The disk is easily handled and applied and conforms to irregularly contoured ulcer beds.

A prospective randomized study comparing multilayer compression therapy alone to treatment with Apligraf in addition to multilayered compression therapy has been performed to assess the efficacy of Apligraf in the treatment of venous ulcers.\textsuperscript{100} More patients treated with Apligraf had ulcer healing at 6 months (63\% vs. 49\%, \( P = .02 \)). The median time to complete ulcer closure was significantly shorter in patients treated with Apligraf (61 days vs. 181 days, \( P = .003 \)). The ulcers that showed the greatest benefit with the living skin construct were ones that were large and deep (>1000 mm\(^2\)) or were longstanding (>6 months). No evidence of rejection or sensitization has been reported in response to Apligraf application.

**Surgical/Interventional Treatment of Chronic Venous Insufficiency**

**Perforator Vein Ligation.** Incompetence of the perforating veins connecting the superficial and deep venous systems of the lower extremities has been implicated in the development of venous ulcers. The classic open technique described by Linton in 1938 for perforator vein ligation has a high incidence of wound complications and has largely been abandoned.\textsuperscript{12} A minimally invasive technique termed subfascial endoscopic perforator vein surgery (SEPS) evolved with improvement of endoscopic equipment.

DUS is performed preoperatively in patients undergoing SEPS to document deep venous competence and to identify perforating veins in the posterior compartment. The patient is positioned on the operating table with the affected leg elevated at 45° to 60°. An Esmarch bandage and a thigh tourniquet are used to exsanguinate the limb. The knee is then flexed, and two small incisions are made in the proximal medial leg away from areas of maximal induration at the ankle. Laparoscopic trocars are then positioned, and the subfascial dissection is performed with a combination of blunt and sharp dissection. Carbon dioxide is then used to insufflate the subfascial space. The thigh tourniquet is inflated to prevent air embolism. The perforators are then identified and doubly clipped and divided. After completion of the procedure, the leg is wrapped in a compression bandage for 5 days postoperatively.

The efficacy of SEPS as a stand-alone procedure in treatment of venous insufficiency is controversial and unproven. In a report from a large North American registry of 146 patients undergoing SEPS\textsuperscript{115} (Fig. 24-20), healing was achieved in 88\% of ulcers (75 of 85) at 1 year. Adjunctive procedures, primarily superficial vein stripping, were performed in 72\% of patients. Ulcer recurrence was predicted to be 16\% at 1 year and 28\% at 2 years by life table analysis. These results are similar to those achieved in some studies with compression therapy alone. A review of several studies from 2003 to 2011 demonstrated, when taken in aggregate, that 2059 limbs with 896 ulcers underwent SEPS and concomitant saphenous vein ablation (70\%) with a 0\% to 16\% complication rate and achieved ulcer healing in 90\% of patients.\textsuperscript{114} There has been a multicenter, prospective, European trial performed in patients with venous ulcers to evaluate the efficacy of SEPS. Post hoc analysis suggested possible benefit for SEPS in certain categories of patients with venous ulcer. Overall, however, primary analysis of the study’s end points indicated no advantage to SEPS in addition to superficial venous surgery and compression in the healing of venous ulcers.\textsuperscript{115} The technique appears to have fallen out of favor in most institutions.

**Superficial Venous Surgery.** Currently it is accepted that superficial venous surgery in addition to compression therapy has a role in the treatment of patients with venous ulcer. The ESCHAR trial was a randomized prospective trial performed in the United Kingdom to evaluate the combination of superficial venous surgery and compression vs. compression alone in the treatment of venous ulcer. Superficial venous surgery had no additive effect to compression alone in the healing of a venous ulcer but significantly reduced venous ulcer recurrence at 4 years. Based on the results of this trial, it is reasonable to offer ablation or removal of the GSV in addition to compression therapy in patients with abnormal saphenous veins and signs and/or symptoms of severe CVI.\textsuperscript{116}

**Deep Venous Valvular Reconstruction.** In the absence of significant deep vein valvular incompetence, saphenous vein stripping and possibly perforator vein ligation can be effective in the treatment of CVI. However, in patients with a combination of superficial and deep vein valvular incompetence, the addition of deep vein valvular reconstruction theoretically may
improve ulcer healing.\textsuperscript{117} Numerous techniques of deep vein valve correction have been reported. These techniques consist of repair of existing valves, transplant of venous segments from the arm, transposition of an incompetent vein onto an adjacent competent vein, and implantation of cryopreserved vein segments including competent valves.

Successful long-term outcomes of 60\% to 80\% have been reported for venous valve reconstructions by internal suture repair.\textsuperscript{117,118} However, among patients who initially had ulceration, 40\% to 50\% still had persistence or recurrence of ulcers in the long term.\textsuperscript{115,116}

Valve transplantation involves replacement of a segment of incompetent femoral vein or popliteal vein with a segment of axillary or brachial vein with competent valves. Early results are similar to those for venous valve reconstruction.\textsuperscript{117,118} However, in the long term, the transplanted venous segments tend to develop incompetence, intimal hyperplasia, and cusp sinus thrombosis with long-term outcomes that are poorer than those for venous valve reconstructions. The outcomes for venous transposition are similar to those for valve transplantation.

Currently, reconstruction techniques for deep venous insufficiency and associated CIV are rarely performed.

**Venous Stenting.** Currently there is great interest in the role of venous stents in the treatment of CVI. Stenotic lesions of the iliac veins, primarily documented with IVUS, are being reported in a very high percentage of patients with edema, lipodermatosclerosis, or ulceration secondary to venous disease. It appears possible to place percutaneous stents in the iliac veins with near 100\% technical success and excellent patency of the stent out to 4 years. Retrospective case series suggest favorable effects on ulcer healing, symptoms of CVI, and quality of life in patients with CVI. The role of venous stenting as a favorable independent procedure in the treatment of patients with CVI remains an area of active investigation.\textsuperscript{119}

**LYMPHEDEMA**

**Pathophysiology**

Lymphedema is extremity swelling that results from a reduction in lymphatic transport and accumulation of lymph within the interstitial space. It is caused by anatomic and or physiologic abnormalities such as lymphatic hypoplasia, functional insufficiency, or absence of lymphatic valves.

The original classification system, described by Allen, \textsuperscript{6} is based on the cause of the lymphedema. Primary lymphedema is further subdivided into congenital lymphedema, lymphedema praecox, and lymphedema tarda. *Congenital lymphedema* may involve a single lower extremity, multiple limbs, the genitalia, or the face. The edema typically develops before 2 years of age and may be associated with specific hereditary syndromes (Turner syndrome, Milroy syndrome, Klippel-Trénaunay-Weber syndrome). *Lymphedema praecox* is the most common form of primary lymphedema, accounting for 94\% of cases. Lymphedema praecox is far more common in women, with the gender ratio favoring women 10:1. The onset is during childhood or the teenage years, and the swelling involves the foot and calf. *Lymphedema tarda* is uncommon, accounting for <10\% of cases of primary lymphedema. The onset of edema is after 35 years of age.

Secondary lymphedema is far more common than primary lymphedema. Secondary lymphedema develops as a result of lymphatic obstruction or disruption. Axillary node dissection leading to lymphedema of the arm is the most common cause of secondary lymphedema in the United States. Other causes of secondary lymphedema include radiation therapy, trauma, infection, and malignancy. Globally, filariasis (an infection caused by *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*) and environmental exposure to minerals in volcanic soil resulting in podoconiosis in barefoot populations are the most common causes of secondary lymphedema.

**Clinical Diagnosis**

In most patients, the diagnosis of lymphedema can be made based on the history and physical examination alone. Patients commonly complain of heaviness and fatigue in the affected extremity. The limb size increases throughout the day and decreases to some extent over the course of the night when the patient is recumbent. The limb, however, never completely normalizes. In the lower extremity, the swelling classically involves the dorsum of the foot, and the toes have a squared-off appearance. In advanced cases, hyperkeratosis of the skin develops, and fluid weeps from lymph-filled vesicles (Fig. 24-21).

Recurrent cellulitis is a common complication of lymphedema. Repeated infection results in further lymphatic damage, worsening existing disease. The clinical presentation of cellulitis ranges from subtle erythema and worsening of edema to a rapidly progressive soft tissue infection with systemic toxicity. Many medical conditions can cause edema. If the symptoms are mild, distinguishing lymphedema from other causes of leg swelling can be difficult. Venous insufficiency is often confused with lymphedema. However, patients with advanced venous insufficiency typically have lipodermatosclerosis in the gaiter region, skin ulceration, and/or varicose veins. Bilateral pitting edema is

**Figure 24-21.** Patient with severe longstanding lymphedema.
typically associated with congestive heart failure, renal failure, or a hypoproteinemic state.

**Radiologic Diagnosis**

**Duplex Ultrasound.** When a patient is evaluated for edema, it is often difficult to distinguish the early stages of lymphedema from venous insufficiency. DUS of the venous system can determine if there is concomitant venous thrombosis or venous reflux, perhaps contributing to extremity edema. The diagnostic modalities discussed in the following sections have limited use in clinical practice. They are invasive and tedious and rarely change the management of a patient with lymphedema. Most physicians rely on the patient’s history and physical examination alone to make the diagnosis of lymphedema.

**Lymphoscintigraphy.** Lymphoscintigraphy has become the most commonly used diagnostic test to identify lymphatic abnormalities. It has largely replaced lymphangiography. A radiolabeled sulfur colloid (technetium 99m sulfur colloid) is injected into the subdermal, interdigital region of the affected limb. The lymphatic transport is monitored with a whole-body gamma camera, and major lymphatics and nodes can be visualized (Fig. 24-22). In normal individuals, tracer activity may be detected in the inguinal region within 15 to 60 minutes. Within 3 hours, uptake should be present in the pelvic and abdominal lymph nodes. In patients with lymphedema, various patterns may be seen on lymphoscintigraphy. There may be delayed or absent transport to the inguinal nodes. Increased cutaneous collaterals may be seen with obstruction of the primary axial channels. There may be localized regions of reduced uptake in patients with prior node dissection or radiation therapy.

**Lymphangiography.** Radiologic lymphangiography is performed by first visualizing the lymphatics by injecting colored dye into the hand or foot. The visualized lymphatic segment is exposed through a small incision and cannulated with a 27- to 30-gauge needle. An oil-based dye is then injected slowly into the lymphatics over several hours. The lymphatic channels and nodes are then visualized with traditional radiographs (Figs. 24-23 and 24-24). Lymphangiography is reserved for patients with lymphangiectasia or lymphatic fistulas, and patients who are being considered for microvascular reconstruction.

**Management**

An important aspect of the management of lymphedema is patient understanding that there is no cure for lymphedema. The primary goals of treatment are to minimize swelling and to prevent recurrent infections. Controlling the chronic limb swelling can improve discomfort, heaviness, and tightness, and potentially reduce the progression of disease. 

**Compression Garments.** Graded compression stockings are widely used in the treatment of lymphedema. The stockings reduce the amount of swelling in the involved extremity by decreasing edema accumulation while the extremity is dependent. When worn daily, compression stockings have been associated with long-term maintenance of reduced limb circumference. They may also protect the tissues against chronically elevated intrinsic pressures, which lead to thickening of the skin and subcutaneous tissue. Compression stockings also offer a degree of protection against external trauma that may lead to cellulitis.

The amount of compression required for controlling lymphedema ranges from 20 to 60 mmHg and varies
Streptococcus are the most common organisms causing soft tissue infection. Aggressive antibiotic therapy and elevation with compression are recommended at the earliest signs or symptoms of cellulitis. The drug of choice is penicillin or a cephalosporin active against Streptococcus for 5 days. In patients with recurrent lymphedema despite methods to reduce edema, treatment with monthly intramuscular injections of benzathine penicillin 1.2 MU, twice-daily erythromycin 250 mg, or penicillin V 1 g daily has proven effective at suppression.128

**Surgery.** A variety of surgical procedures have been devised for the treatment of lymphedema. Surgical treatment involves either excision of extra tissue127 or anastomosis of a lymphatic vessel to another lymphatic or vein.126 In excisional procedures, part or all of the edematous tissue is removed. This does not improve lymphatic drainage but debulks redundant tissue. The microsurgical procedures involve the creation of a lymphatic-lymphatic or lymphaticovenous anastomosis, which theoretically improves lymphatic drainage. No long-term follow-up data are available for these interventions, and therefore operative therapy for lymphedema is not well accepted worldwide. Furthermore, operative intervention can further obliterate lymphatic channels, worsening the edema.129

**SUMMARY**

Lymphedema is a chronic condition caused by ineffective lymphatic transport, which results in edema and skin damage. Lymphedema is not curable, but the symptoms and long-term effects can be controlled with a combination of elastic compression stockings, limb elevation, pneumatic compression, and massage. Controlling the edema protects the skin and potentially prevents cellulitis.

SURGICAL ANATOMY

The esophagus is a muscular tube that starts as the continuation of the pharynx and ends as the cardia of the stomach. When the head is in a normal anatomic position, the transition from pharynx to esophagus occurs at the lower border of the sixth cervical vertebra. Topographically this corresponds to the cricoid cartilage anteriorly and the palpable transverse process of the sixth cervical vertebra laterally (Fig. 25-1). The esophagus is firmly attached at its upper end to the cricoid cartilage and at its lower end to the diaphragm; during swallowing, the proximal points of fixation move cranially the distance of one cervical vertebral body.

The esophagus lies in the midline, with a deviation to the left in the lower portion of the neck and upper portion of the thorax, and returns to the midline in the midportion of the thorax near the bifurcation of the trachea (Fig. 25-2). In the lower portion of the thorax, the esophagus again deviates to the left and anteriorly to pass through the diaphragmatic hiatus.
Three normal areas of esophageal narrowing are evident on the barium esophagogram or during esophagoscopy. The uppermost narrowing is located at the entrance into the esophagus and is caused by the cricopharyngeal muscle. Its luminal diameter is 1.5 cm, and it is the narrowest point of the esophagus. The middle narrowing is due to an indentation of the anterior and left lateral esophageal wall caused by the crossing of the left main stem bronchus and aortic arch. The luminal diameter at this point is 1.6 cm. The lowermost narrowing is at the hiatus of the diaphragm and is caused by the gastroesophageal sphincter mechanism. The luminal diameter at this point varies somewhat, depending on the distention of the esophagus by the passage of food, but has been measured at 1.6 to 1.9 cm. These normal constrictions tend to hold up swallowed foreign objects, and the overlying mucosa is subject to injury by swallowed corrosive liquids due to their slow passage through these areas.

Figure 25-3 shows the average distance in centimeters measured during endoscopic examination between the incisor teeth and the cricopharyngeus, aortic arch, and cardia of the stomach. Manometrically, the length of the esophagus between

---

**Key Point**

1. Benign esophageal disease is common and is best evaluated with thorough physiologic testing (high resolution esophageal motility, 24 hour ambulatory pH measurement, and/or esophageal impedance testing) and anatomic testing (esophagoscopy, video esophagography, and/or CT scanning).

2. GERD is the most common disease of the gastrointestinal tract for which patients seek medical therapy. When GERD symptoms (heartburn, regurgitation, chest pain, and/or supraesophageal symptoms) are troublesome despite adequately dosed PPI, surgical correction may be indicated.

3. Barrett’s esophagus is the transformation of the distal esophageal epithelium from squamous to a specialized columnar epithelium capable of further neoplastic progression. The detection of Barrett’s esophagus on endoscopy and biopsy increases the future risk of cancer by >40x compared to individuals without Barrett’s esophagus.

4. Giant hiatal hernia, otherwise known as paraesophageal hernia, should be repaired when symptomatic or associated with iron deficiency anemia. Laparoscopic hiatal hernia repair with fundoplication is the most common approach to repair.

5. Achalasia is the most common primary esophageal motor disorder. It is characterized by an absence of peristalsis and a hypertensive nonrelaxing lower esophageal sphincter. It is best treated with laparoscopic Heller myotomy and partial fundoplication.

6. Most esophageal cancer presents with dysphagia, at which time it has invaded the muscularis of the esophagus and is often associated with lymph node metastases. The preferred treatment at this stage is multimodality therapy with chemoradiation therapy followed by open or minimally invasive esophagectomy.

the lower border of the cricopharyngeus and upper border of the lower sphincter varies according to the height of the individual.

The pharyngeal musculature consists of three broad, flat, overlapping fan-shaped constrictors (Fig. 25–4). The opening of the esophagus is collared by the cricopharyngeal muscle, which

**Figure 25-3.** Important clinical endoscopic measurements of the esophagus in adults. (Reproduced with permission from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus, in Shields TW (ed): General Thoracic Surgery, 3rd ed. Philadelphia: Lea & Febiger, 1989, p 78.)

arises from both sides of the cricoid cartilage of the larynx and forms a continuous transverse muscle band without an interruption by a median raphe. The fibers of this muscle blend inseparably with those of the inferior pharyngeal constrictor above and the inner circular muscle fibers of the esophagus below. Some investigators believe that the cricopharyngeus is part of the inferior constrictor; that is, the inferior constrictor has two parts, an upper or retrothyroid portion having diagonal fibers, and a lower or retroesophageal portion having transverse fibers. Keith in 1910 showed that these two parts of the same muscle serve totally different functions. The retroesophageal portion serves as the upper sphincter of the esophagus and relaxes when the retrothyroid portion contracts, to force the swallowed bolus from the pharynx into the esophagus.

The cervical portion of the esophagus is approximately 5 cm long and descends between the trachea and the vertebral column, from the level of the sixth cervical vertebra to the level of the interspace between the first and second thoracic vertebrae posteriorly, or the level of the suprasternal notch anteriorly. The recurrent laryngeal nerves lie in the right and left grooves between the trachea and the esophagus. The left recurrent nerve lies somewhat closer to the esophagus than the right, owing to the slight deviation of the esophagus to the left, and the more lateral course of the right recurrent nerve around the right subclavian artery. Laterally, on the left and right sides of the cervical esophagus are the carotid sheaths and the lobes of the thyroid gland.

The thoracic portion of the esophagus is approximately 20 cm long. It starts at the thoracic inlet. In the upper portion of the thorax, it is in intimate relationship with the posterior wall of the trachea and the prevertebral fascia. Just above the tracheal bifurcation, the esophagus passes to the right of the aorta. This anatomic positioning can cause a notch indentation in its left lateral wall on a barium swallow radiogram. Immediately below this notch, the esophagus crosses both the bifurcation of the trachea and the left main stem bronchus, owing to the slight deviation of the terminal portion of the trachea to the right by the aorta (Fig. 25-5). From there down, the esophagus passes over the posterior surface of the subcarinal lymph nodes (LN5), and then descends over the pericardium of the left atrium to reach the diaphragmatic hiatus (Fig. 25-6). From the bifurcation of the trachea downward, both the vagal nerves and the esophageal nerve plexus lie on the muscular wall of the esophagus.

Dorsally, the thoracic esophagus follows the curvature of the spine and remains in close contact with the vertebral bodies. From the eighth thoracic vertebra downward, the esophagus moves vertically away from the spine to pass through the hiatus of the diaphragm. The thoracic duct passes through the hiatus of the diaphragm on the anterior surface of the vertebral column behind the aorta and under the right crus. In the thorax, the thoracic duct lies dorsal to the esophagus between the azygos vein on the right and the descending thoracic aorta on the left.

The abdominal portion of the esophagus is approximately 2 cm long and includes a portion of the lower esophageal sphincter (LES). It starts as the esophagus passes through the diaphragmatic hiatus and is surrounded by the phrenoesophageal membrane, a fibroelastic ligament arising from the subdiaphragmatic fascia as a continuation of the transversalis fascia lining the abdomen (Fig. 25-7). The upper leaf of the membrane attaches itself in a circumferential fashion around the esophagus, about 1 to 2 cm above the level of the hiatus. These fibers blend in with the elastic-containing adventitia of the abdominal esophagus and the cardia of the stomach. This portion of the esophagus is subjected to the positive-pressure environment of the abdomen.

The musculature of the esophagus can be divided into an outer longitudinal and an inner circular layer. The upper 2 to 6 cm of the esophagus contains only striated muscle fibers. From then on, smooth muscle fibers gradually become more abundant. Most clinically significant esophageal motility disorders involve only the smooth muscle in the lower two-thirds of the esophagus. When a surgical esophageal myotomy is indicated, the incision needs to extend only this distance.

The longitudinal muscle fibers originate from a cricoesophageal tendon arising from the dorsal upper edge of the anteriorly located cricoid cartilage. The two bundles of muscle diverge and meet in the midline on the posterior wall of the esophagus about 3 cm below the cricoid (see Fig. 25-4).
From this point on, the entire circumference of the esophagus is covered by a layer of longitudinal muscle fibers. This configuration of the longitudinal muscle fibers around the most proximal part of the esophagus leaves a V-shaped area in the posterior wall covered only with circular muscle fibers. Contraction of the longitudinal muscle fibers shortens the esophagus. The circular muscle layer of the esophagus is thicker than the outer longitudinal layer. In situ, the geometry of the circular muscle is helical and makes the peristalsis of the esophagus assume a worm-like drive, as opposed to segmental and sequential squeezing. As a consequence, severe motor abnormalities of the esophagus assume a corkscrew-like pattern on the barium swallow radiogram.

The cervical portion of the esophagus receives its main blood supply from the inferior thyroid artery. The thoracic portion receives its blood supply from the bronchial arteries, with 75% of individuals having one right-sided and two left-sided branches. Two esophageal branches arise directly from the aorta.

The abdominal portion of the esophagus receives its blood supply from the ascending branch of the left gastric artery and from inferior phrenic arteries (Fig. 25-8). On entering the wall of the esophagus, the arteries assume a T-shaped division to form a longitudinal plexus, giving rise to an intramural vascular network in the muscular and submucosal layers. As a consequence, the esophagus can be mobilized from the stomach to the level of the aortic arch without fear of devascularization and ischemic necrosis. Caution should be exercised as to the extent...
of esophageal mobilization in patients who have had a previous thyroidectomy with ligation of the inferior thyroid arteries proximal to the origin of the esophageal branches.

Blood from the capillaries of the esophagus flows into a submucosal venous plexus, and then into a periesophageal venous plexus from which the esophageal veins originate. In the cervical region, the esophageal veins empty into the inferior thyroid vein; in the thoracic region, they empty into the bronchial, azygos, or hemiazygos veins; and in the abdominal region, they empty into the coronary vein (Fig. 25-9). The submucosal venous networks of the esophagus and stomach are in continuity with each other, and, in patients with portal venous obstruction, this communication functions as a collateral pathway for portal blood to enter the superior vena cava via the azygos vein.

The parasympathetic innervation of the pharynx and esophagus is provided mainly by the vagus nerves. The constrictor muscles of the pharynx receive branches from the pharyngeal plexus, which is on the posterior lateral surface of the middle constrictor muscle, and is formed by pharyngeal branches of the vagus nerves with a small contribution from cranial nerves IX and XI (Fig. 25-10). The cricopharyngeal sphincter and the cervical portion of the esophagus receive branches from both recurrent laryngeal nerves, which originate from the vagus nerves—the right recurrent nerve at the lower margin of the subclavian artery and the left at the lower margin of the aortic arch. They are slung dorsally around these vessels and ascend in the groove between the esophagus and trachea, giving branches to each. Damage to these nerves interferes not only with the function of the vocal cords, but also with the function of the cricopharyngeal sphincter and the motility of the cervical esophagus, predisposing the individual to pulmonary aspiration on swallowing.

Afferent visceral sensory pain fibers from the esophagus end without synapse in the first four segments of the thoracic spinal cord, using a combination of sympathetic and vagal pathways. These pathways are also occupied by afferent visceral sensory fibers from the heart; hence, both organs have similar symptomatology.

The lymphatics located in the submucosa of the esophagus are so dense and interconnected that they constitute a single plexus (Fig. 25-11). There are more lymph vessels than blood vessels.
capillaries in the submucosa. Lymph flow in the submucosal plexus runs in a longitudinal direction, and, on injection of a contrast medium, the longitudinal spread is seen to be about six times that of the transverse spread. In the upper two-thirds of the esophagus, the lymphatic flow is mostly cephalad, and, in the lower third, caudad. In the thoracic portion of the esophagus, the submucosal lymph plexus extends over a long distance in a longitudinal direction before penetrating the muscle layer to enter lymph vessels in the adventitia. As a consequence of this nonsegmental lymph drainage, a primary tumor can extend for a considerable length superiorly or inferiorly in the submucosal plexus. Consequently, free tumor cells can follow the submucosal lymphatic plexus in either direction for a long distance before they pass through the muscularis and on into the regional LNs. The cervical esophagus has more direct segmental lymph drainage into the regional nodes, and, as a result, lesions in this portion of the esophagus have less submucosal extension and a more regionalized lymphatic spread.

The efferent lymphatics from the cervical esophagus drain into the paratracheal and deep cervical LNs, and those from the upper thoracic esophagus empty mainly into the paratracheal LNs. Efferent lymphatics from the lower thoracic esophagus drain into the subcarinal nodes and nodes in the inferior pulmonary ligaments. The superior gastric nodes receive lymph not only from the abdominal portion of the esophagus, but also from the adjacent lower thoracic segment.

**PHYSIOLOGY**

**Swallowing Mechanism**

The act of alimentation requires the passage of food and drink from the mouth into the stomach. One-third of this distance consists of the mouth and hypopharynx, and two-thirds is made up by the esophagus. To comprehend the mechanics of alimentation, it is useful to visualize the gullet as a mechanical model in which the tongue and pharynx function as a piston pump with three valves, and the body of the esophagus and cardia function as a worm-drive pump with a single valve. The three valves in the pharyngeal cylinder are the soft palate, epiglottis, and cricopharyngeus. The valve of the esophageal pump is the LES. Failure of the valves or the pumps leads to abnormalities in swallowing—that is, difficulty in food propulsion from mouth to stomach—or regurgitation of gastric contents into the esophagus or pharynx.

Food is taken into the mouth in a variety of bite sizes, where it is broken up, mixed with saliva, and lubricated. Once initiated, swallowing is entirely a reflex act. When food is ready for swallowing, the tongue, acting like a piston, moves the bolus into the posterior oropharynx and forces it into the hypopharynx (Fig. 25-12). Concomitantly with the posterior movement of the tongue, the soft palate is elevated, thereby closing the passage between the oropharynx and nasopharynx. This partitioning prevents pressure generated in the oropharynx from being dissipated through the nose. When the soft palate is paralyzed, for example, after a cerebrovascular accident, food is commonly regurgitated into the nasopharynx. During swallowing, the hyoid bone moves upward and anteriorly, elevating the larynx and opening the retrolaryngeal space, bringing the epiglottis under the tongue (see Fig. 25-12). The backward tilt of the epiglottis covers the opening of the larynx to prevent aspiration. The entire pharyngeal part of swallowing occurs within 1.5 seconds.

The entire pharyngeal part of swallowing occurs within 1.5 seconds. The entire pharyngeal part of swallowing occurs within 1.5 seconds. During swallowing, the pressure in the hypopharynx rises abruptly, to at least 60 mmHg, due to the backward movement of the tongue and contraction of the posterior pharyngeal constrictors. A sizable pressure difference develops between the hypopharyngeal pressure and the less-than-atmospheric midesophageal or intrathoracic pressure (Fig. 25-13). This pressure gradient speeds the movement of food from the hypopharynx into the stomach oropharyngeal phase of swallowing. (Reproduced with permission from DeMeester TR, Stein HJ, Fuchs KH: Physiologic diagnostic studies, in Zuidema GD, Orringer MB (eds): Shackelford’s Surgery of the Alimentary Tract, 3rd ed., Vol. I. Philadelphia: W.B. Saunders, 1991, p 95. Copyright Elsevier.)

![Figure 25-12. Sequence of events during the oropharyngeal phase of swallowing.](image)

![Figure 25-13. Resting pressure profile of the foregut showing the pressure differential between the atmospheric pharyngeal pressure (P) and the less-than-atmospheric midesophageal pressure (E) and greater-than-atmospheric intragastric pressure (G), with the interposed high pressure zones of the cricopharyngeus (C) and distal esophageal sphincter (DES). The necessity for relaxation of the cricopharyngeus and DES pressure to move a bolus into the stomach is apparent. Esophageal work occurs when a bolus is pushed from the midesophageal area (E), with a pressure less than atmospheric, into the stomach, which has a pressure greater than atmospheric (G).](image)
into the esophagus when the cricopharyngeus or upper esophageal sphincter relaxes. The bolus is both propelled by peristaltic contraction of the posterior pharyngeal constrictors and sucked into the thoracic esophagus. Critical to receiving the bolus is the compliance of the cervical esophagus; when compliance is lost due to muscle pathology, dysphagia can result. The upper esophageal sphincter closes within 0.5 second of the initiation of the swallow, with the immediate closing pressure reaching approximately twice the resting level of 30 mmHg. The postrelaxation contraction continues down the esophagus as a peristaltic wave (Fig. 25-14). The high closing pressure and the initiation of the peristaltic wave prevents reflux of the bolus from the esophagus back into the pharynx. After the peristaltic wave has passed farther down the esophagus, the pressure in the upper esophageal sphincter returns to its resting level.

Swallowing can be started at will, or it can be reflexively elicited by the stimulation of areas in the mouth and pharynx, among them the anterior and posterior tonsillar pillars or the posterior lateral walls of the hypopharynx. Theafferent sensory nerves of the pharynx are the glossopharyngeal nerves and the superior laryngeal branches of the vagus nerves. Once aroused by stimuli entering via these nerves, the swallowing center in the medulla coordinates the complete act of swallowing by discharging impulses through cranial nerves V, VII, X, XI, and XII, as well as the motor neurons of C1 to C3. Discharges through these nerves occur in a rather specific pattern and last for approximately 0.5 second. Little is known about the organization of the swallowing center, except that it can trigger swallowing after a variety of different inputs, but the response is always a rigidly ordered pattern of outflow. Following a cerebrovascular accident, this coordinated outflow may be altered, causing mild to severe abnormalities of swallowing. In more severe injury, swallowing can be grossly disrupted, leading to repetitive aspiration.

The striated muscles of the cricopharyngeus and the upper one-third of the esophagus are activated by efferent motor fibers distributed through the vagus nerve and its recurrent laryngeal branches. The integrity of innervation is required for the cricopharyngeus to relax in coordination with the pharyngeal contraction, and resume its resting tone once a bolus has entered the upper esophagus. Operative damage to the innervation can interfere with laryngeal, cricopharyngeal, and upper esophageal function, and predispose the patient to aspiration.

The pharyngeal activity in swallowing initiates the esophageal phase. The body of the esophagus functions as a worm-drive propulsive pump due to the helical arrangement of its circular muscles, and is responsible for transferring a bolus of food into the stomach. The esophageal phases of swallowing represents esophageal work done during alimentation, in that food is moved into the stomach from a negative-pressure environment of –6 mm Hg intrathoracic pressure, to a positive-pressure environment of 6 mm Hg intra-abdominal pressure, or over a gradient of 12 mm Hg (see Fig. 25-13). Effective and coordinated smooth muscle function in the lower one-third of the esophagus is therefore important in pumping the food across this gradient.

The peristaltic wave generates an occlusive pressure varying from 30 to 120 mmHg (Fig. 25-14). The wave rises to a peak in 1 second, lasts at the peak for about 0.5 second, and then subsides in about 1.5 seconds. The whole course of the rise and fall of occlusive pressure may occupy one point in the esophagus for 3 to 5 seconds. The peak of a primary peristaltic contraction initiated by a swallow (primary peristalsis) moves down the esophagus at 2 to 4 cm/s and reaches the distal esophagus about 9 seconds after swallowing starts. Consecutive swallows produce similar primary peristaltic waves, but when the act of swallowing is rapidly repeated, the esophagus remains relaxed and the peristaltic wave occurs only after the last movement of the pharynx. Progress of the wave in the esophagus is caused by sequential activation of its muscles, initiated by efferent vagal nerve fibers arising in the swallowing center.

Continuity of the esophageal muscle is not necessary for sequential activation if the nerves are intact. If the muscles, but not the nerves, are cut across, the pressure wave begins distally below the cut as it dies out at the proximal end above the cut. This allows a sleeve resection of the esophagus to be done without destroying its normal function. Afferent impulses from receptors within the esophageal wall are not essential for progress of the coordinated wave. Afferent nerves, however, do go to the swallowing center from the esophagus, because, if the esophagus is distended at any point, a contractual wave begins with a forceful closure of the upper esophageal sphincter and sweeps down the esophagus. This secondary contraction occurs without any movements of the mouth or pharynx. Secondary peristalsis can occur as an independent local reflex to clear the esophagus of ingested material left behind after the passage of the primary wave. Current studies suggest that secondary peristalsis is not as common as once thought.

Despite the powerful occlusive pressure, the propulsive force of the esophagus is relatively feeble. If a subject attempts to swallow a bolus attached by a string to a counterweight, the maximum weight that can be overcome is 5 to 10 g.

![Figure 25-14. Intraluminal esophageal pressures in response to swallowing. (Reproduced with permission from Waters PF, DeMeester TR: Foregut motor disorders and their surgical management. Med Clin North Am 65:1238, 1981. Copyright Elsevier.)](image-url)
Orderly contractions of the muscular wall and anchoring of the esophagus at its inferior end are necessary for efficient aboral propulsion to occur. Loss of the inferior anchor, as occurs with a large hiatal hernia, can lead to inefficient propulsion.

The LES provides a pressure barrier between the esophagus and stomach and acts as the valve on the worm-drive pump of the esophageal body. Although an anatomically distinct LES has been difficult to identify, microdissection studies show that, in humans, the sphincter-like function is related to the architecture of the muscle fibers at the junction of the esophageal tube with the gastric pouch (Fig. 25-15). The sphincter actively remains closed to prevent reflux of gastric contents into the esophagus and opens by a relaxation that coincides with a pharyngeal swallow (see Fig. 25-14). The LES pressure returns to its resting level after the peristaltic wave has passed through the esophagus. Consequently, reflux of gastric juice that may occur through the open valve during a swallow is cleared back into the stomach.

If the pharyngeal swallow does not initiate a peristaltic contraction, then the coincident relaxation of the LES is unguarded and reflux of gastric juice can occur. This may be an explanation for the observation of spontaneous lower esophageal relaxation, thought by some to be a causative factor in gastroesophageal reflux disease (GERD). The power of the worm-drive pump of the esophageal body is insufficient to force open a valve that does not relax. In dogs, a bilateral cervical parasympathetic blockade abolishes the relaxation of the LES that occurs with pharyngeal swallowing or distention of the esophagus. Consequently, vagal function appears to be important in coordinating the relaxation of the LES with esophageal contraction.

The antireflux mechanism in human beings is composed of three components: a mechanically effective LES, efficient esophageal clearance, and an adequately functioning gastric reservoir. A defect of any one of these three components can lead to increased esophageal exposure to gastric juice and the development of mucosal injury.

**Physiologic Reflux**

On 24-hour esophageal pH monitoring, healthy individuals have occasional episodes of gastroesophageal reflux. This physiologic reflux is more common when awake and in the upright position than during sleep in the supine position. When reflux of gastric juice occurs, normal subjects rapidly clear the acid gastric juice from the esophagus regardless of their position.

There are several explanations for the observation that physiologic reflux in normal subjects is more common when they are awake and in the upright position than during sleep in the supine position. First, reflux episodes occur in healthy volunteers primarily during transient losses of the gastroesophageal barrier, which may be due to a relaxation of the LES or intra-gastric pressure overcoming sphincter pressure. Gastric juice can also reflux when a swallow-induced relaxation of the LES is not protected by an oncoming peristaltic wave. The average frequency of these “unguarded moments” or of transient losses of the gastroesophageal barrier is far less while asleep and in the supine position than while awake and in the upright position. Consequently, there are fewer opportunities for reflux to occur in the supine position. Second, in the upright position, there is a 12-mmHg pressure gradient between the resting, positive intra-abdominal pressure measured in the stomach and the most negative intrathoracic pressure measured in the esophagus at midthoracic level. This gradient favors the flow of gastric juice up into the thoracic esophagus when upright. The gradient diminishes in the supine position. Third, the LES pressure in normal subjects is significantly higher in the supine position than in the upright position. This is due to the apposition of the hydrostatic pressure of the abdomen to the abdominal portion of the sphincter when supine. In the upright position, the abdominal pressure surrounding the sphincter is negative compared with atmospheric pressure, and, as expected, the abdominal pressure gradually increases the more caudally it is measured. This pressure gradient tends to move the gastric contents toward the cardia and encourages the occurrence of reflux into the esophagus when the individual is upright. In contrast, in the supine position, the gastroesophageal pressure gradient diminishes, and the abdominal hydrostatic pressure under the diaphragm increases, causing an increase in sphincter pressure and a more competent cardio-

The LES has intrinsic myogenic tone, which is modulated by neural and hormonal mechanisms. Alpha-adrenergic neurotransmitters or beta blockers stimulate the LES, and alpha blockers and beta stimulants decrease its pressure. It is not clear to what extent cholinergic nerve activity controls LES pressure. The vagus nerve carries both excitatory and inhibitory fibers to the esophagus and sphincter. The hormones gastrin and motilin have been shown to increase LES pressure; and cholecystokinin, estrogen, glucagon, progesterone, somatostatin, and secretin decrease LES pressure. The peptides bombesin, 1-enkephalin,
and substance P increase LES pressure; and calcitonin gene-related peptide, gastric inhibitory peptide, neuropeptide Y, and vasoactive intestinal polypeptide decrease LES pressure. Some pharmacologic agents such as antacids, cholinergics, agonists, domperidone, metoclopramide, and prostaglandin \( F_2 \) are known to increase LES pressure; and anticholinergics, barbiturates, calcium channel blockers, caffeine, diazepam, dopamine, meperidine, prostaglandin \( E_1 \) and \( E_2 \), and theophylline decrease LES pressure. Peppermint, chocolate, coffee, ethanol, and fat are all associated with decreased LES pressure and may be responsible for esophageal symptoms after a sumptuous meal.

**ASSESSMENT OF ESOPHAGEAL FUNCTION**

A thorough understanding of the patient’s underlying anatomic and functional deficits before making therapeutic decisions is fundamental to the successful treatment of esophageal disease. The diagnostic tests, as presently used, may be divided into four broad groups: (a) tests to detect structural abnormalities of the esophagus; (b) tests to detect functional abnormalities of the esophagus; (c) tests to detect increased esophageal exposure to gastric juice; and (d) tests of duodenogastric function as they relate to esophageal disease.

**Tests to Detect Structural Abnormalities**

**Endoscopic Evaluation.** The first diagnostic test in patients with suspected esophageal disease is usually upper gastrointestinal endoscopy. This allows assessment and biopsy of the mucosa of the stomach and the esophagus, as well as the diagnosis and assessment of obstructing lesions in the upper gastrointestinal tract. In any patient complaining of dysphagia, esophagoscopy is indicated, even in the face of a normal radiographic study.

For the initial endoscopic assessment, the flexible fiberoptic esophagoscope is the instrument of choice because of its technical ease, patient acceptance, and the ability to simultaneously assess the stomach and duodenum. Rigid endoscopy is now only rarely required, mainly for the disimpaction of difficult foreign bodies impacted in the esophagus.

When GERD is the suspected diagnosis, particular attention should be paid to detecting the presence of esophagitis and Barrett’s columnar-lined esophagus (CLE). When esophageal esophagitis is seen, severity and the length of esophagitis involved are recorded. Many different grading systems have been proposed. In a commonly used system, Grade I esophagitis is defined as small, circular, nonconfluent erosions (Fig. 25-16). Grade II esophagitis is defined by the presence of linear erosions lined with granulation tissue that bleeds easily when touched. Grade III esophagitis represents a more advanced stage, in which the linear erosions coalesce into circumferential loss of the epithelium and the mucosa may take a “cobblestone” appearance. Grade IV esophagitis is the presence of a stricture. Its severity can be assessed by the ease of passing a 36F esoscope. When a stricture is observed, the severity of the esophagitis above it should be recorded. The absence of esophagitis above a stricture suggests a chemical-induced injury or a neoplasm as a cause. The latter should always be considered and is ruled out only by evaluation of a tissue biopsy of adequate size. It should be remembered that gastroesophageal reflux is not always associated with visible mucosal abnormalities, and patients can experience significant reflux symptoms, despite an apparently normal endoscopy examination.

Barrett’s esophagus (BE) is a condition in which the tubular esophagus is lined with columnar epithelium, as opposed to the normal squamous epithelium (Fig. 25-16). Histologically, it appears as intestinal metaplasia (IM). It is suspected at endoscopy when there is difficulty in visualizing the squamocolumnar junction at its normal location, and by the appearance of a redder, more luxuriant mucosa than is normally seen in the lower esophagus. Its presence is confirmed by biopsy. Multiple biopsy specimens should be taken in a cephalad direction to determine the level at which the junction of Barrett’s epithelium with normal squamous mucosa occurs. BE is susceptible to ulceration, bleeding, stricture formation, and, most important, malignant degeneration. The earliest sign of the latter is high grade dysplasia or intramucosal adenocarcinoma (Fig. 25-16). These dysplastic changes have a patchy distribution, so a minimum of four biopsy samples spaced 2 cm apart should be taken from the Barrett’s-lined portion of the esophagus. Changes seen in one biopsy are significant. Nishimaki has determined that the tumors occur in an area of specialized columnar epithelium near the squamocolumnar junction in 85% of patients, and within 2 cm of the squamocolumnar junction in virtually all patients. Particular attention should be focused on this area in patients suspected of harboring a carcinoma.

Abnormalities of the gastroesophageal flap valve can be visualized by retroflexion of the endoscope. Hill has graded the appearance of the gastroesophageal valve from I to IV according to the degree of unfolding or deterioration of the normal valve architecture (Fig. 25-17). The appearance of the valve correlates with the presence of increased esophageal acid exposure, occurring predominantly in patients with Grade III and IV valves.

A hiatal hernia is endoscopically confirmed by finding a pouch lined with gastric rugal folds lying 2 cm or more above the margins of the diaphragmatic crura, identified by having the patient sniff. A hernia is best demonstrated with the stomach fully insufflated and the gastroesophageal junction observed with a retroflexed endoscope. A prominent sliding hiatal hernia frequently is associated with increased esophageal exposure to gastric juice. When a paraesophageal hernia (PEH) is observed, particular attention is taken to exclude a gastric (Cameron’s) ulcer or gastritis within the pouch. The intragastric retroflex or J maneuver is important in evaluating the full circumference of the mucosal lining of the herniated stomach.

When an esophageal diverticulum is seen, it should be carefully explored with the flexible endoscope to exclude ulceration or neoplasia. When a submucosal mass is identified, biopsy specimens are usually not performed. At the time of surgical resection, a submucosal leiomyoma or reduplication cyst can generally be dissected away from the intact mucosa, but if a biopsy sample is taken, the mucosa may become fixed to the underlying abnormality. This complicates the surgical dissection by increasing the risk of mucosal perforation. Endoscopic ultrasound provides a better method for evaluating these lesions.

**Radiographic Evaluation.** Barium swallow evaluation is undertaken selectively to assess anatomy and motility. The anatomy of large hiatal hernias are more clearly demonstrated by contrast radiology than endoscopy, and the presence of coordinated esophageal peristalsis can be determined by observing several individual swallows of barium traversing the entire length of the organ, with the patient in the horizontal position. Hiatal hernias are best demonstrated with the patient prone because the increased intra-abdominal pressure produced in this
position promotes displacement of the esophagogastric junction above the diaphragm. To detect lower esophageal narrowing, such as rings and strictures, fully distended views of the esophagogastric region are crucial. The density of the barium used to study the esophagus can potentially affect the accuracy of the examination. Esophageal disorders shown clearly by a full-column technique include circumferential carcinomas, peptic strictures, large esophageal ulcers, and hiatal hernias. A small hiatal hernia is usually not associated with significant symptoms or illness, and its presence is an irrelevant finding unless the hiatal hernia is large (Fig. 25-18), or the hernia is of the paraesophageal variety. Lesions extrinsic but adjacent to the esophagus can be reliably detected by the full-column technique if they contact the distended esophageal wall. Conversely, a number of important disorders may go undetected if this is the sole technique used to examine the esophagus. These include small esophageal neoplasms, mild esophagitis, and esophageal varices. Thus, the full-column technique should be supplemented with mucosal relief or double-contrast films to enhance detection of these smaller or more subtle lesions.

Motion-recording techniques greatly aid in evaluating functional disorders of the pharyngoesophageal and esophageal phases of swallowing. The technique and indications for cine- and videoradiography will be discussed in the section entitled Video- and Cineradiography, as they are more useful to evaluate function and seldom used to detect structural abnormalities.

The radiographic assessment of the esophagus is not complete unless the entire stomach and duodenum have been examined. A gastric or duodenal ulcer, partially obstructing gastric neoplasm, or scarred duodenum and pylorus may contribute significantly to symptoms otherwise attributable to an esophageal abnormality.
Figure 25-17. A. Grade I flap valve appearance. Note the ridge of tissue that is closely approximated to the shaft of the retroflexed endoscope. It extends 3–4 cm along the lesser curve. B. Grade II flap valve appearance. The ridge is slightly less well defined than in grade I and it opens rarely with respiration and closes promptly. C. Grade III flap valve appearance. The ridge is barely present, and there is often failure to close around the endoscope. It is nearly always accompanied by a hiatal hernia. D. Grade IV flap valve appearance. There is no muscular ridge at all. The gastroesophageal valve stays open all the time, and squamous epithelium can often be seen from the retroflexed position. A hiatal hernia is always present. (Reproduced with permission from Hill LD, Kozarek RA, et al.: The gastroesophageal flap valve. In vitro and in vivo observations. Gastrointest Endosc. 44:541, 1996. Copyright Elsevier.)
When a patient’s complaints include dysphagia and no obstructing lesion is seen on the barium swallow, it is useful to have the patient swallow a barium-impregnated marshmallow, a barium-soaked piece of bread, or a hamburger mixed with barium. This test may bring out a functional disturbance in esophageal transport that can be missed when liquid barium is used.

Tests to Detect Functional Abnormalities
In many patients with symptoms of an esophageal disorder, standard radiographic and endoscopic evaluation fails to demonstrate a structural abnormality. In these situations, esophageal function tests are necessary to identify a functional disorder.

Stationary Manometry. Esophageal manometry is a widely used technique to examine the motor function of the esophagus and its sphincters. Manometry is indicated whenever a motor abnormality of the esophagus is suspected on the basis of complaints of dysphagia, odynophagia, or noncardiac chest pain, and the barium swallow or endoscopy does not show a clear structural abnormality. Esophageal manometry is particularly necessary to confirm the diagnosis of specific primary esophageal motility disorders (i.e., achalasia, diffuse esophageal spasm [DES], nutcracker esophagus, and hypertensive LES). It also identifies nonspecific esophageal motility abnormalities and motility disorders secondary to systemic disease such as scleroderma, dermatomyositis, polymyositis, or mixed connective tissue disease. In patients with symptomatic GERD, manometry of the esophageal body can identify a mechanically defective LES, and evaluate the adequacy of esophageal peristalsis and contraction amplitude. Manometry has become an essential tool in the preoperative evaluation of patients before antireflux surgery, guiding selection of the appropriate procedure based upon the patient’s underlying esophageal function, and excluding patients with achalasia who can be misdiagnosed with gastroesophageal reflux when clinical and endoscopic parameters alone are used for diagnosis.

Esophageal manometry is performed using electronic, pressure-sensitive transducers located within the catheter, or water-perfused catheters with lateral side holes attached to transducers outside the body. The traditional catheter consists of a train of five pressure transducers or five or more water-perfused tubes bound together. The transducers or lateral openings are placed at 5-cm intervals from the tip and oriented radially at 72° from each other around the circumference of the catheter. A special catheter assembly consisting of four lateral openings at the same level, oriented at 90° to each other, is of special use in measuring the three-dimensional vector volume of the LES. Other specially designed catheters can be used to assess the upper sphincter.

As the pressure-sensitive station is brought across the gastroesophageal junction (GEJ), a rise in pressure above the gastric baseline signals the beginning of the LES. The respiratory inversion point is identified when the positive excursions that occur in the abdominal cavity with breathing change to negative deflections in the thorax. The respiratory inversion point serves as a reference point at which the amplitude of LES pressure and the length of the sphincter exposed to abdominal pressure...
are measured. As the pressure-sensitive station is withdrawn into the body of the esophagus, the upper border of the LES is identified by the drop in pressure to the esophageal baseline. From these measurements, the pressure, abdominal length, and overall length of the sphincter are determined (Fig. 25-19). To account for the asymmetry of the sphincter (Fig. 25-20), the pressure profile is repeated with each of the five radially oriented transducers, and the average values for sphincter pressure above gastric baseline, overall sphincter length, and abdominal length of the sphincter are calculated.

Table 25-1 shows the values for these parameters in 50 normal volunteers without subjective or objective evidence of a foregut disorder. The level at which a deficiency in the mechanics of the LES occurs was defined by comparing the frequency distribution of these values in the 50 healthy volunteers with a population of similarly studied patients with symptoms of GERD. The presence of increased esophageal exposure to gastric juice was documented by 24-hour esophageal pH monitoring. Based on these studies, a mechanically defective sphincter is identified by having one or more of the following characteristics: an average LES pressure of \(< 6 \text{ mmHg}\), an average length of 1 cm or less, and/or an average overall sphincter length of 2 cm or less. Compared with the normal volunteers, these values are below the 2.5 percentile for sphincter pressure and overall length and for abdominal length.

To assess the relaxation and postrelaxation contraction of the LES, a pressure transducer is positioned within the high-pressure zone, with the distal transducer located in the stomach and the proximal transducer within the esophageal body. Ten wet swallows (5 mL water each) are performed. The normal pressure of the LES should drop to the level of gastric pressure during each wet swallow.

The function of the esophageal body is assessed with the five pressure transducers located in the esophagus. The standard procedure is to locate the most proximal pressure transducer 1 cm below the well-defined cricopharyngeal sphincter, allowing a pressure response throughout the whole esophagus to be obtained on one swallow. Ten wet swallows are recorded. Amplitude, duration, and morphology of contractions following each swallow are calculated at all recorded levels of the esophageal body. The delay between the onset and peak of esophageal contractions at the various levels of the esophagus is used to calculate the speed of wave propagation. The relationship of the esophageal contractions following a swallow is classified as peristaltic or simultaneous. The data are used to identify motor disorders of the esophagus.

**SD** = standard deviation.

The position, length, and pressure of the cricopharyngeal sphincter are assessed with a stationary pull-through technique similar to that used for the LES. The manometric catheter is withdrawn in 0.5-cm intervals from the upper esophagus through the upper esophageal sphincter region into the pharynx. The relaxation of the upper esophageal sphincter is studied by straddling the eight pressure transducers across the sphincter so that some are in the pharynx and some are in the upper esophagus. High-speed graphic recordings (50 mm/s) are necessary to obtain an assessment of the coordination of cricopharyngeal relaxation with hypopharyngeal contraction. It has been difficult to consistently demonstrate a motility abnormality in patients with pharyngoesophageal disorders.

**High-Resolution Manometry.** Esophageal manometry was introduced into clinical practice in the 1970s and, until recently, has changed little. In 1991, Ray Clouse introduced the concept of improving conventional manometry by increasing the number of recording sites and adding a three-dimensional assessment. This “high-resolution manometry” is a variant of the conventional manometry in which multiple, circumferential recording sites are used, in essence creating a “map” of the esophagus and its sphincters. High-resolution catheters contain 36 miniaturized pressure sensors positioned every centimeter along the length of the catheter. The vast amount of data generated by these sensors is then processed and presented in traditional linear plots or as a visually enhanced spatiotemporal video tracing that is readily interpreted (Fig. 25-21).

Simultaneous acquisition of data for the upper esophageal sphincter, esophageal body, LES, and gastric pressure minimizes the movement artifacts and study time associated with conventional esophageal manometry. Powerful, computer-based, and easy-to-use tools give unprecedented data analysis capability. This technology significantly enhances esophageal diagnostics, bringing it into the realm of “image” based studies. High-resolution manometry may allow the identification of focal motor abnormalities previously overlooked. It has enhanced the ability to predict bolus propagation and increased sensitivity in the measurement of pressure gradients.

**Esophageal Impedance.** New technology recently introduced into the clinical realm allows measurement of esophageal function and gastroesophageal reflux in a way that has heretofore not been possible. An intraluminal electrical impedance catheter has recently been developed for the measurement of GI function. Impedance is the ratio of voltage to current, and is a measure of the electrical conductivity of a hollow organ and its contents. Intraluminal electrical impedance is inversely proportional to the electrical conductivity of the luminal contents and the crosssectional area of the lumen. Air has a very low electrical conductivity and, therefore, high impedance. Saliva and food cause an impedance decrease because of their increased conductivity. Luminal dilatation results in a decrease in impedance, whereas luminal contraction yields an impedance increase. Investigators have established the impedance waveform characteristics that define esophageal bolus transport. This allows for the characterization of both esophageal function, via quantification of bolus transport, and gastroesophageal reflux (Fig. 25-22). The probe measures impedance between adjacent electrodes, with measuring segments located at 2, 4, 6, 8, 14, and 16 cm from the distal tip. An extremely low electric current of 0.00025 μA is transmitted across the electrodes at a frequency of 1 to 2 kHz and is limited to 8 μA. This is below the stimulation threshold for nerves and muscles, and is three orders of magnitude below the threshold of cardiac stimulation. A standard pH electrode is located 5 cm from the distal tip, so that the acidic or nonacidic nature of refluxate can be correlated with the number of reflux events.

Esophageal impedance has been validated as an appropriate method for the evaluation of GI function and is becoming increasingly used for the diagnosis of gastroesophageal reflux. It has been compared to cineradiography showing that impedance waves correspond well with actual bolus transport illustrated by radiography. Bolus entry, transit, and exit can be clearly identified by impedance changes in the corresponding measuring segments. Preliminary studies comparing standard esophageal manometry with impedance measurements in healthy volunteers have been performed, and have validated the ability of esophageal impedance to correlate with peristaltic wave progression and bolus length. Clinical investigators are beginning to examine and validate impedance measurement in the evaluation of esophageal and small intestinal pathophysiology.

It is increasingly recognized that 24-hour pH monitoring as the historical gold standard for diagnosing and quantifying gastroesophageal reflux has significant limitations. With 24-hour ambulatory pH testing, reflux is defined as a drop in the pH below 4, which effectively “blinds” the test to reflux occurring at higher pH values. Furthermore, in patients with persistent symptoms on proton pump inhibitor (PPI) therapy, pH monitoring has limited use as it can only detect abnormal acid reflux (pH <4), the occurrence of which has been altered by the antisecretory medication. Given that PPI antisecretory therapy is highly effective in neutralizing gastric acid, the question of whether persistent symptoms are a result of persistent acid reflux, nonacid reflux, or are not reflux related becomes a key issue in surgical decision making. Until recently, this differentiation could not be made. A reliable method for detecting both acid and nonacid reflux has potential to define these populations of patients and thus improve patient selection for antireflux surgery. The recent introduction of multichannel intraluminal impedance technology allows the measurement of both acid and nonacid reflux, with potential to significantly enhance diagnostic accuracy.

Using this technology, Balaji and colleagues showed that most gastroesophageal reflux remains despite acid suppression. Impedance pH may be particularly useful in evaluating patients with persistent symptoms despite PPI treatment, patients with respiratory symptoms, and postoperative patients who are having symptoms that are elusive to diagnosis.

**Esophageal Transit Scintigraphy.** The esophageal transit of a 10-mL water bolus containing technetium-99m (99mTc) sulfur colloid can be recorded with a gamma camera. Using this technique, delayed bolus transit has been shown in patients with a variety of esophageal motor disorders, including achalasia, scleroderma, DES, and nutcracker esophagus.

**Video- and Cineradiography**

High-speed cinematic or video recording of radiographic studies allows re-evaluation by reviewing the studies at various speeds. This technique is more useful than manometry in the evaluation of the pharyngeal phase of swallowing. Observations suggesting oropharyngeal or cricopharyngeal dysfunction include misdirection of barium into the trachea or nasopharynx, prominence of the cricopharyngeal muscle, a Zenker’s diverticulum, a narrow pharyngoesophageal segment, and stasis of the

Figure 25-21D. High-resolution manometry motility study in patient with achalasia. Note the complete absence of esophageal body peristalsis, and the lack of relaxation of the lower esophageal sphincter. Pressure measurements are recorded with color coding (red = high; blue = low). LES = lower esophageal sphincter; PIP = pressure inversion point; UES = upper esophageal sphincter.
Figure 25-21E. High-resolution manometry motility study in patient with diffuse esophageal spasm. Note the very high amplitude contractions in the esophageal body. Pressure measurements are recorded with color coding (red = high; blue = low). LES = lower esophageal sphincter; PIP = pressure inversion point; UES = upper esophageal sphincter.
contrast medium in the valleculae or hypopharyngeal recesses (Fig. 25-23). These findings are usually not specific, but rather common manifestations of neuromuscular disorders affecting the pharyngoesophageal area. Studies using liquid barium, barium-impregnated solids, or radiopaque pills aid the evaluation of normal and abnormal motility in the esophageal body. Loss of the normal stripping wave or segmentation of the barium column with the patient in the recumbent position correlates with abnormal motility of the esophageal body. In addition, structural abnormalities such as small diverticula, webs, and minimal extrinsic impressions of the esophagus may be recognized only with motion-recording techniques. The simultaneous computerized capture of videofluoroscopic images and manometric tracings is now available, and is referred to as manofluorography. Manofluorographic studies allow precise correlation of the anatomic events, such as opening of the upper esophageal sphincter, with manometric observations, such as sphincter relaxation. Manofluorography, although not widely available, is presently the best means available to evaluate complex functional abnormalities.

**Tests to Detect Increased Exposure to Gastric Juice**

24-Hour Ambulatory pH Monitoring. The most direct method of measuring increased esophageal exposure to gastric juice is by an indwelling pH electrode, or, more recently, via a radiotelemetric pH monitoring capsule that can be clipped to the esophageal mucosa. The latter consists of an antimony pH electrode fitted inside a small, capsule-shaped device accompanied by a battery and electronics that allow 48-hour monitoring and transmission of the pH data via transcutaneous radio telemetry to a waist-mounted data logger. The device can be introduced either transorally or transnasally, and clipped to the esophageal mucosa using endoscopic fastening techniques. It passes spontaneously within 1 to 2 weeks. Prolonged monitoring of esophageal pH is performed by placing the pH probe or telemetry capsule 5 cm above the manometrically measured upper border of the distal sphincter for 24 hours. It measures the actual time the esophageal mucosa is exposed to gastric juice, measures the

St. Louis: Mosby, 1987, p 345. Copyright Elsevier.)
ability of the esophagus to clear refluxed acid, and correlates esophageal acid exposure with the patient’s symptoms. A 24- to 48-hour period is necessary so that measurements can be made over one or two complete circadian cycles. This allows measuring the effect of physiologic activity, such as eating or sleeping, on the reflux of gastric juice into the esophagus (Fig. 25-24).

The 24-hour esophageal pH monitoring should not be considered a test for reflux, but rather a measurement of the esophageal exposure to gastric juice. The measurement is expressed by the time the esophageal pH was below a given threshold during the 24-hour period. This single assessment, although concise, does not reflect how the exposure has occurred; that is, did it occur in a few long episodes or several short episodes? Consequently, two other assessments are necessary: the frequency of the reflux episodes and their duration.

The units used to express esophageal exposure to gastric juice are: (a) cumulative time the esophageal pH is below a chosen threshold, expressed as the percentage of the total, upright, and supine monitored time; (b) frequency of reflux episodes below a chosen threshold, expressed as number of episodes per 24 hours; and (c) duration of the episodes, expressed as the number of episodes >5 minutes per 24 hours, and the time in minutes of the longest episode recorded. Table 25-2 shows the normal values for these components of the 24-hour record at the whole-number pH threshold derived from 50 normal asymptomatic subjects. The upper limits of normal were established at the ninety-fifth percentile. Most centers use pH 4 as the threshold.

The components’ 24-hour pH record are then combined into one expression of the overall esophageal acid exposure below a pH threshold; the pH score is calculated by using the standard deviation (SD) of the mean of each of the six components measured in the 50 normal subjects as a weighting factor. By accepting an abstract zero level two SDs below the mean, the data measured in normal subjects could be treated as though they had a normal distribution. Thus, any measured patient value could be referenced to this zero point, and, in turn, be awarded points based on whether it was below or above the normal mean value for that component, according to this formula:

\[
\text{Component score} = \frac{\text{Point value} - \text{mean}}{\text{SD} + 1}
\]

The upper limits of normal for the composite score for each whole-number pH threshold are shown in Table 25-3.

The detection of increased esophageal exposure to acid gastric juice is more dependable than the detection of increased exposure to alkaline gastric juice. The latter is suggested by an increased alkaline exposure time above pH 7 or 8. Increased

exposure in this pH range can be caused by abnormal calibration of the pH recorder; dental infection, which increases salivary pH; esophageal obstruction, which results in static pools of saliva with an increase in pH secondary to bacterial overgrowth; or regurgitation of alkaline gastric juice into the esophagus. Using a properly calibrated probe, in the absence of dental infections or esophageal obstruction, the percentage of time the pH is measured above 7 correlates with the concentration of bile acids continuously aspirated over a 24-hour period.

When done in a test population with an equal distribution of normal healthy subjects and patients with the classic reflux symptoms and a defective sphincter, 24-hour esophageal pH monitoring had a sensitivity and specificity of 96%. (Sensitivity is the ability to detect a disease when known to be present; specificity is the ability to exclude the disease when known to be absent.) This gave a predictive value of a positive and negative test of 96%, and an overall accuracy of 96%. Based on these studies and extensive clinical experience, 24-hour esophageal pH monitoring has emerged as the gold standard for the diagnosis of GERD.

Catheter-based, 24-hour, ambulatory, esophageal pH monitoring does have a significant drawback of the physical presence of a transnasal catheter that must be worn for 24 hours. Although most doctors ask patients to go about their normal activities of daily living, many do not comply due to embarrassment about the catheter or from discomfort. The recent development of a wireless capsule, which can be implanted in the esophagus and record pH data for 48 hours, has significantly changed patient satisfaction with the procedure.

The Bravo pH Capsule (Medtronics, Minneapolis, MN) measures pH levels in the esophagus and transmits continuous esophageal pH readings to a receiver worn on the patient’s belt or waistband (Fig. 25-27). Symptoms that the patient experiences are recorded in a diary and/or by pressing buttons on the receiver unit. Generally, 48 hours of pH data are measured with this probe. A recent study has shown that the addition of a second day of pH monitoring increased the sensitivity of pH measurement by 22%. The capsule eventually detaches and passes through the digestive tract in 5 to 7 days.

**Radiographic Detection of Gastroesophageal Reflux.** The definition of radiographic gastroesophageal reflux varies depending on whether reflux is spontaneous or induced by various maneuvers. In only about 40% of patients with classic symptoms of GERD is spontaneous reflux (i.e., reflux of barium from the stomach into the esophagus with the patient in the upright position) observed by the radiologist. In most patients who show spontaneous reflux on radiography, the diagnosis of increased esophageal acid exposure is confirmed by 24-hour esophageal pH monitoring. Therefore, the radiographic demonstration of spontaneous regurgitation of barium into the esophagus in the upright position is a reliable indicator that reflux is present. However, failure to see this does not indicate the absence of disease, and for this reason this test is rarely relied on for clinical diagnosis.

**Tests of Duodenogastric Function**

Esophageal disorders are frequently associated with abnormalities of duodenogastric function. Abnormalities of the gastric reservoir or increased gastric acid secretion can be responsible for increased esophageal exposure to gastric juice. Reflux of alkaline duodenal juice, including bile salts, pancreatic enzymes, and bicarbonate, is thought to have a role in the pathogenesis of esophagitis and complicated Barrett’s esophagus. Furthermore, functional disorders of the esophagus are often not confined to the esophagus alone, but are associated with functional disorders of the rest of the foregut (i.e., stomach and duodenum). Tests of duodenogastric function that are helpful to investigate esophageal symptoms include gastric emptying studies, gastric acid analysis, and cholescintigraphy (for the diagnosis of pathologic duodenogastric reflux). The single test of 24-hour gastric pH monitoring can be used to identify gastric hypersecretion and imply the presence of duodenogastric reflux and delayed gastric emptying.

**Gastric Emptying.** Gastric emptying studies are performed with radionuclide-labeled meals. Emptying of solids and liquids can be assessed simultaneously when both phases are marked with different tracers. After ingestion of a labeled standard meal, gamma camera images of the stomach are obtained at 5- to 15-minute intervals for 1.5 to 2 hours. After correction for decay, the counts in the gastric area are plotted as the percentage of total counts at the start of the imaging. The resulting emptying curve can be compared with data obtained in normal volunteers. In general, normal subjects will empty 59% of a meal within 90 minutes. Although delayed gastric emptying is often associated with gastroesophageal reflux, in general delayed emptying does not correlate with a poorer clinical outcome after antireflux surgery, and it should not be considered a contraindication to surgical treatment.

**24-Hour Gastric pH Monitoring.** Monitoring is performed over a complete circadian cycle with a pH electrode placed 5 cm below the manometrically located LES. The patient is fully ambulatory during the test and is encouraged to perform normal daily activity. The gastric pH profile is assessed separately for the meal, postprandial period, and fasting period. The latter is divided into the time spent upright and supine.

The interpretation of continuous gastric pH recordings is more difficult than that of esophageal pH recordings. This is because the gastric pH environment is determined by a complex interplay of acid secretion; mucus secretion; ingested food; swallowed saliva; regurgitated duodenal, pancreatic, and biliary secretions; and the effectiveness of the mixing and evacuation of the chyme. Using 24-hour gastric pH monitoring to evaluate the gastric secretory state is based on studies that have shown that a good correlation exists between increased basal acid output on standard gastric acid analysis, and a left shift on the frequency distribution histogram of gastric pH recordings during the supine fasting period. The evaluation of gastric emptying by 24-hour gastric pH monitoring is based on studies demonstrating a good correlation between the emptying of a solid meal and the duration of the postprandial plateau and decline phase of the gastric pH record.

Using 24-hour gastric pH monitoring to evaluate duodenogastric reflux is based on the observation that reflux of alkaline duodenal juice into the stomach can alkalinate the gastric pH environment. The measurement is not straightforward because of the effect of meals, and reduction in acid secretion can result in changes in gastric pH that mimic alkaline reflux episodes. To overcome this problem, computerized measurements of the number and height of alkalinating peaks, the baseline pH, the postprandial pH plateau, and the pattern of pH decline from the plateau can be used to identify the probability of duodenogastric reflux. The results are presented as an overall score that indicates the likelihood of pathologic duodenogastric reflux.
Initial data indicate that this approach has a higher sensitivity and specificity for the diagnosis of pathologic duodenogastric reflux than scintigraphic methods do.

Combined 24-hour esophageal and gastric pH monitoring can identify excessive alkaline duodenogastric and alkaline gastroesophageal reflux in symptomatic patients. The combined tracings can often identify simultaneous gastric and esophageal alkalization, suggesting a duodenal origin for the esophageal alkaline exposure (Fig. 25-25).

**GASTROESOPHAGEAL REFLUX DISEASE**

GERD was not recognized as a significant clinical problem until the mid-1930s and was not identified as a precipitating cause for esophagitis until after World War II. In the early twenty-first century, it has grown to be a very common problem and now accounts for a majority of esophageal pathology. It is recognized as a chronic disease, and when medical therapy is required, it is often lifelong treatment. Recent efforts at the development of various endoscopic antireflux interventions, although innovative, have not been successful in consistently controlling gastroesophageal reflux. Antireflux surgery is an effective and long-term therapy and is the only treatment that is able to restore the gastroesophageal barrier. Despite the common prevalence of GERD, it can be one of the most challenging diagnostic and therapeutic problems in clinical medicine. A contributing factor to this is the lack of a universally accepted definition of the disease.

The most simplistic approach is to define the disease by its symptoms. However, symptoms thought to be indicative of GERD, such as heartburn or acid regurgitation, are very common in the general population and many individuals consider them to be normal and do not seek medical attention. Even when excessive, these symptoms are not specific for gastroesophageal reflux. They can be caused by other diseases such as achalasia, DES, esophageal carcinoma, pyloric stenosis, cholelithiasis, gastritis, gastric or duodenal ulcer, and coronary artery disease.

A thorough, structured evaluation of the patient’s symptoms is essential before any therapy, particularly any form of esophageal surgery. The presence and severity of both typical symptoms of heartburn, regurgitation, and dysphagia, and atypical symptoms of cough, hoarseness, chest pain, asthma, and aspiration should be discussed with the patient in detail. Many of these atypical symptoms may not be esophageal related and hence will not improve and may even worsen with antireflux surgery.

Heartburn is generally defined as a substernal burning-type discomfort, beginning in the epigastrium and radiating upward. It is often aggravated by meals, spicy or fatty foods, chocolate, alcohol, and coffee and can be worse in the supine position. It is commonly, although not universally, relieved by antacid or antsecretory medications. Epidemiologic studies...
Nevens and colleagues evaluated the ability to distinguish between the two etiologies, particularly on clinical grounds alone. Nevens and colleagues investigated the ultimate diagnosis in 10,689 patients presenting to an emergency room with acute chest pain. Approximately 17% were found to have acute ischemia, 6% stable angina, 21% other cardiac causes, and 55% had noncardiac causes. They concluded that the majority of people presenting to the emergency room with chest pain do not have an underlying cardiac etiology for their symptoms. Chest pain precipitated by meals, occurring at night while supine, nonradiating, responsive to antacid medication, or accompanied by other symptoms suggesting esophageal disease such as dysphagia or regurgitation should trigger the thought of possible esophageal origin. Further, the distinction between heartburn and chest pain is also difficult and largely dependent upon the individual patient. One person's heartburn is another's chest pain.

The precise mechanisms accounting for the generation of symptoms secondary to esophageal pathology remain unclear. Considerable insight has been acquired, however. Investigations into the effect of luminal content, esophageal distention and muscular function, neural pathways, and brain localization have provided a basic understanding of the stimuli responsible for symptom generation. It is also clear that the visceroneural pathways of the foregut are complexly intertwined with that of the tracheobronchial tree and heart. This fact accounts for the common overlap of clinical presentations with diverse disease processes in upper GI, cardiac, and pulmonary systems.

have shown that heartburn occurs monthly in as many as 40% to 50% of the Western population. The occurrence of heartburn at night and its effect on quality of life have recently been highlighted by a Gallup poll conducted by the American Gastroenterologic Society (Table 25-4). Regurgitation, the effortless return of acid or bitter gastric contents into the chest, pharynx, or mouth, is highly suggestive of foregut pathology. It is often particularly severe at night when supine or when bending over and can be secondary to either an incompetent or obstructed GEJ. With the later, as in achalasia, the regurgitant is often bland, as if food was put into a blender. When questioned, most patients can distinguish the two. It is the regurgitation of gastric contents that may result in associated pulmonary symptoms, including cough, hoarseness, asthma, and recurrent pneumonia. Bronchospasm can be precipitated by esophageal acidification and cough by either acid stimulation or distention of the esophagus.

Dysphagia, or difficulty swallowing, is a relatively nonspecific term but arguably the most specific symptom of foregut disease. It can be a sign of underlying malignancy and should be aggressively investigated until a diagnosis is established. Dysphagia refers to the sensation of difficulty in the passage of food from the mouth to the stomach and can be divided into oropharyngeal and esophageal etiologies. Oropharyngeal dysphagia is characterized by difficulty transferring food out of the mouth into the esophagus, nasal regurgitation, and/or aspiration. Esophageal dysphagia refers to the sensation of food sticking in the lower chest or epigastrium. This may or may not be accompanied by pain (odynophagia) that will be relieved by the passage of the bolus.

Chest pain, although commonly and appropriately attributed to cardiac disease, is frequently secondary to esophageal pathology as well. As early as 1982, DeMeester and associates showed that nearly 50% of patients with severe chest pain, normal cardiac function, and normal coronary arteriograms had positive 24-hour pH studies, implicating gastroesophageal reflux as the underlying etiology. Exercise-induced gastroesophageal reflux is well known to occur, and may result in exertional chest pain similar to angina. It can be quite difficult, if not impossible, to distinguish between the two etiologies, particularly on clinical grounds alone. Nevens and colleagues evaluated the ability of experienced cardiologists to differentiate pain of cardiac vs. esophageal origin. Of 248 patients initially seen by cardiologists, 185 were thought to have typical angina and 63 atypical chest pain. Forty eight (26%) of those thought to have classic angina had normal coronary angiograms and 16 of the 63 with atypical pain had abnormal angiogram. Thus, the cardiologists’ clinical impression was wrong 25% of the time. Finally, Pope and associates investigated the ultimate diagnosis in 10,689 patients presenting to an emergency room with acute chest pain. Approximately 17% were found to have acute ischemia, 6% stable angina, 21% other cardiac causes, and 55% had noncardiac causes. They concluded that the majority of people presenting to the emergency room with chest pain do not have an underlying cardiac etiology for their symptoms. Chest pain precipitated by meals, occurring at night while supine, nonradiating, responsive to antacid medication, or accompanied by other symptoms suggesting esophageal disease such as dysphagia or regurgitation should trigger the thought of possible esophageal origin. Further, the distinction between heartburn and chest pain is also difficult and largely dependent upon the individual patient. One person’s heartburn is another’s chest pain.

The Human Antireflux Mechanism and the Pathophysiology of Gastroesophageal Reflux Disease

There is a high-pressure zone located at the esophagogastric junction in humans. Although this is typically referred to as the lower esophageal “sphincter,” there are no distinct anatomical landmarks which define its beginning and end. Architecturally speaking, there is a specialized thickening in this region that is made up of the collar sling musculature and the clasp fibers. The collar sling is located on the greater curvature side of the junction, and the clasp fibers are located on the lesser curvature side. These muscles remain in tonic opposition until the act of swallowing, whereupon receptive relaxation occurs allowing passage of a food bolus into the stomach. In addition, the LES will also open when the gastric fundus is distended with gas and liquid, thus resulting in an unfolding of the valve and enabling venting of gas (a belch). Whether physiologic or pathologic, the common denominator for most episodes of gastroesophageal reflux is the loss of the high-pressure zone and thus, a decrease in the resistance it imparts to the retrograde flow of gastric juice into the esophageal body. The primary cause of GERD is secondary to the permanent attenuation of the collar sling musculature, with a resultant opening of the gastric cardia and loss of the high-pressure zone as measured with esophageal manometry.

The Lower Esophageal Sphincter. As defined by esophageal manometry, there are three characteristics of the LES that work in unison to maintain its barrier function. These characteristics include the resting LES pressure, its overall length, and the intra-abdominal length that is exposed to the positive pressure environment of the abdomen (Table 25-5). The resistance to gastroesophageal reflux is a function of both the resting LES pressure and length over which this pressure is exerted. Thus, as the sphincter becomes shorter, a higher pressure will be required in order to prevent a given amount of reflux (Fig. 25-26).

Much like the neck of a balloon as it is inflated, as the stomach fills and distends, sphincter length decreases. Therefore, if the overall length of the sphincter is permanently short from repeated distention of the fundus secondary to large volume meals, then with minimal episodes of gastric distention and pressure, there will be insufficient sphincter length for the barrier to remain competent, and reflux will occur.

A third characteristic of the LES that impacts its ability to prevent reflux is its position about the diaphragm. It is important that a portion of the total length of the LES be exposed to the effects of an intra-abdominal pressure. That is, during periods of elevated intra-abdominal pressure, the resistance of the barrier would be overcome if pressure were not applied equally to both the LES and stomach simultaneously. Thus, in the presence of a hiatal hernia, the sphincter resides entirely within the chest cavity and cannot respond to an increase in intra-abdominal pressure because the pinch valve mechanism is lost and gastroesophageal reflux is more liable to occur.

Therefore, a permanently defective sphincter is defined by one or more of the following characteristics: An LES with a mean resting pressure of less than 6 mmHg, an overall sphincter length of <2 cm, and intra-abdominal sphincter length of <1 cm. Compared to normal subjects without GERD these values are below the 2.5 percentile for each parameter. The most common cause of a defective sphincter is an inadequate abdominal length.

Once the sphincter is permanently defective, this condition is irreversible, and although esophageal mucosal injury may be healed with antisecretory medication, reflux will continue to occur. Additionally, the presence of a defective LES may be associated with reduced esophageal body function and thus decrease clearance times of refluxed material. In addition, with the progressive loss of effective esophageal clearance the patient may be predisposed to severe mucosal injury, volume regurgitation, aspiration, and pulmonary failure. Reflux may occur in the face of a normal LES resting pressure. This condition is usually due to a functional problem of gastric emptying or excessive air swallowing. These conditions may lead to gastric distention, increased intra-gastric pressure, a resultant shortening or unfolding of the LES, and subsequent reflux. The mechanism by which gastric distention contributes to LES unfolding provides a mechanical explanation for “transient LES relaxation.” It is thought that with repeated gastric distention secondary to large meal volume or chronic air swallowing, there is repeated unfolding of the LES and subsequent attenuation of the collar sling musculature. It is at this point that the physiologic and normal mechanism of gastric venting is replaced with pathologic and severe postprandial reflux disease. In addition, patients with GERD will increase the frequency of swallowing in an effort to neutralize the refluxed acid with their saliva (pH 7.0). This phenomenon leads to increased air swallowing and further gastric distention thus, compounding the problem. Therefore GERD may have its origins in the stomach secondary to gastric distention due to overeating, and this may be further compounded by the ingestion of fatty meals, which result in delayed gastric emptying.

Relationship Between Hiatal Hernia and Gastroesophageal Reflux Disease. As the collar sling musculature and clasp fibers become attenuated with repeated gastric distention, the esophagogastric junction begins to assume an “upside down funnel” appearance, with progressive opening of the acute angle of His. This in turn may result in attenuation and stretching of the phrenoesophageal ligament, with subsequent enlargement of the hiatal opening and axial herniation. There is a high degree of correlation between reflux threshold and the degree of hiatal herniation (Fig. 25-27).

![Figure 25-26](image1.png)  
Figure 25-26. As the esophageal sphincter becomes shorter, increased pressure is necessary to maintain competence. LES = lower esophageal sphincter.

![Figure 25-27](image2.png)  
Figure 25-27. Yield pressure of the lower esophageal sphincter decreases as hiatal hernia size increases.
It is believed that the source of postprandial esophageal acid exposure results from a “pocket of acid” at the esophageal gastric junction that is unaffected by the buffering action of the meal. This same process is thought to occur in patients with endoscopy-negative dyspepsia and normal conventional esophageal pH monitoring at a location of 5 cm proximal to the upper border of the LES.

**Summary.** It is believed that GERD has its origins within the stomach. Distention of the fundus occurs because of overeating and delayed gastric emptying secondary to a high-fat diet. The resultant distention causes “unrolling” of the sphincter by the expanding fundus, and this subsequently exposes the squamous epithelium in the region of the distal LES to gastric juice. Repeated exposure results in inflammation and the development of columnar epithelium at the cardia. This is the initial step of the development of carditis and explains why in early disease esophagitis is mild and commonly limited to the very distal aspect of the esophagus. The patient attempts to compensate for this by increased swallowing, allowing the saliva to neutralize the refluxed gastric juice and thus, alleviate the discomfort induced by the reflux event. The increased swallowing results in a viscous cycle of increased gastric distention and thus further exposure and repetitive injury to the distal esophagus. The development of carditis explains the complaint of epigas-tric pain often experienced by patients with early reflux disease. Additionally this process can lead to a fibrotic mucosal ring located at the squamocolumnar junction, which is termed a “Schatzki ring,” and may result in dysphagia. This inflammatory process may extend into muscularis propria and thus result in a progressive loss in the length and pressure of the LES. This explanation for the pathophysiology of GERD is supported by the observation that severe esophagitis is almost always associated with a defective LES.

**Complications Associated with Gastroesophageal Reflux Disease**

The complications of gastroesophageal reflux disease may result from the direct injurious effects of gastric fluid on the mucosa, larynx, or respiratory epithelium. Complications due to repetitive reflux are esophagitis, strictures, and BE; repetitive aspiration may lead to progressive pulmonary fibrosis. The severity of the complications is directly related to the prevalence of a structurally defective sphincter (Table 25-6). The observation that a structurally defective sphincter occurs in 42% of patients without complications (most of whom have one or two components failed) suggests that disease may be confined to the sphincter due to compensation by a vigorously contracting esophageal body. Eventually, all three components of the sphincter fail, allowing unrestricted reflux of gastric juice into the esophagus and overwhelming its normal clearance mechanisms. This leads to esophageal mucosal injury with progressive deterioration of esophageal contractility, as is commonly seen in patients with strictures and BE. The loss of esophageal clearance increases the potential for regurgitation into the pharynx with aspiration.

The potential injurious components that reflux into the esophagus include gastric secretions such as acid and pepsin, as well as biliary and pancreatic secretions that regurgitate from the duodenum into the stomach. There is a considerable body of experimental evidence to indicate that maximal epithelial injury occurs during exposure to bile salts combined with acid and pepsin. These studies have shown that acid alone does minimal damage to the esophageal mucosa, but the combination of acid and pepsin is highly deleterious. Similarly, the reflux of duodenal juice alone does little damage to the mucosa, although the combination of duodenal juice and gastric acid is particularly noxious.

Experimental animal studies have shown that the reflux of duodenal contents into the esophagus enhances inflammation, increases the prevalence of Barrett’s esophagus, and results in the development of esophageal adenocarcinoma. The component of duodenal juice thought to be most damaging is bile acids. For bile acids to injure mucosal cells, it is necessary that they be both soluble and un-ionized, so that the un-ionized, nonpolar form may enter mucosal cells. Before the entry of bile into the GI tract, 98% of bile acids are conjugated with either taurine or glycine in a ratio of about 3:1. Conjugation increases the solubility and ionization of bile acids by lowering their pKₐ. At the normal duodenal pH of approximately 7, over 90% of bile salts are in solution and completely ionized. At pH ranges from 2 to 7, there is a mixture of the ionized salt and the lipophilic, non-ionized acid. Acidification of bile to below pH 2 results in an irreversible bile acid precipitation. Consequently, under normal physiologic conditions, bile acids precipitate and are of minimal consequence when an acid gastric environment exists. On the other hand, in a more alkaline gastric environment, such as occurs with excessive duodenogastric reflux and after acid suppression therapy or vagotomy and partial or total gastrectomy, bile salts remain in solution, are partially dissociated, and when refluxed into the esophagus can cause severe mucosal injury by crossing the cell membrane and damaging the mitochondria.

Complications of gastroesophageal reflux such as esophagitis, strictures, and Barrett’s metaplasia occur in the presence of two predisposing factors: a mechanically defective LES and an increased esophageal exposure to fluid containing duodenal content which includes bile and pancreatic juice. The duodenal origin of esophageal contents in patients with an increased exposure to a pH >7 has previously been confirmed by esophageal

*Grade more severe with defective cardiag.

aspiration studies (Fig. 25-28). Studies have clarified and expanded these observations by measuring esophageal bilirubin exposure over a 24-hour period as a marker for the presence of duodenal juice. Direct measurement of esophageal bilirubin exposure as a marker for duodenal juice has shown that 58% of patients with GERD have increased esophageal exposure to duodenal juice, and that this exposure occurs most commonly when the esophageal pH is between 4 and 7 (Fig. 25-29). These earlier studies have been confirmed by other studies which measure volume reflux using impedance technology.

The fact that the combination of refluxed gastric and duodenal juice is more noxious to the esophageal mucosa than gastric juice alone may explain the repeated observation that 25% of patients with reflux esophagitis develop recurrent or progressive mucosal damage, often despite medical therapy (Fig. 25-30). A potential reason is that acid suppression therapy is unable to consistently maintain the pH of refluxed gastric and duodenal juice above the range of 6. Lapses into pH ranges from 2 to 6 encourage the formation of undissociated, nonpolarized, soluble bile acids, which are capable of penetrating the cell wall and injuring mucosal cells. To ensure that bile acids remain completely ionized in their polarized form, and thus unable to penetrate the cell, requires that the pH of the refluxed material be maintained above 7, 24 hours a day, 7 days a week, for the patient’s lifetime. In practice, this would not only be impractical but likely impossible, unless very high doses of medications were used. The use of lesser doses would allow esophageal mucosal damage to occur while the patient was relatively asymptomatic. Antireflux operative procedures re-establish the barrier between stomach and esophagus, protecting the esophagus from damage in patients with mixed gastroesophageal reflux.

If reflux of gastric juice is allowed to persist and sustained or repetitive esophageal injury occurs, two sequelae can result. First, a luminal stricture can develop from submucosal and
eventually intramural fibrosis. Second, the tubular esophagus may become replaced with columnar epithelium. The columnar epithelium is resistant to acid and is associated with the alleviation of the complaint of heartburn. This columnar epithelium often becomes intestinalized, identified histologically by the presence of goblet cells. This specialized IM is currently required for the diagnosis of BE. Endoscopically, BE can be quiescent or associated with complications of esophagitis, stricture, Barrett’s ulceration, and dysplasia. The complications associated with BE may be due to the continuous irritation from refluxed duodenogastric juice. This continued injury is pH dependent and may be modified by medical therapy. The incidence of metaplastic Barrett’s epithelium becoming dysplastic and progressing to adenocarcinoma is approximately 0.2% to 0.5% per year.

An esophageal stricture can be associated with severe esophagitis or BE. In the latter situation, it occurs at the site of maximal inflammatory injury (i.e., the columnar-squamous epithelial interface). As the columnar epithelium advances into the area of inflammation, the inflammation extends higher into the proximal esophagus, and the site of the stricture moves progressively up the esophagus. Patients who have a stricture in the absence of Barrett’s esophagus should have the presence of gastroesophageal reflux documented before the presence of the stricture is ascribed to reflux esophagitis. In patients with normal acid exposure, the stricture may be due to cancer or a drug-induced chemical injury, the latter resulting from the lodgment of a capsule or tablet in the distal esophagus. In such patients, dilation usually corrects the problem of dysphagia. Heartburn, which may have occurred only because of the chemical injury, need not be treated. It is also possible for drug-induced injuries to occur in patients who have underlying esophagitis and a distal esophageal stricture secondary to gastroesophageal reflux. In this situation, a long, string-like stricture progressively develops as a result of repetitive caustic injury from capsule or tablet lodgment on top of an initial reflux stricture. These strictures are often resistant to dilation. The incidence of this problem has lessened since the introduction of proton pump inhibitor medication.

**Metaplastic (Barrett’s Esophagus) and Neoplastic (Adenocarcinoma) Complications**

The condition whereby the tubular esophagus is lined with columnar epithelium rather than squamous epithelium was first described by Norman Barrett in 1950. He incorrectly believed it to be congenital in origin. It is now realized that it is an acquired abnormality, occurs in 10% to 15% of patients with GERD, and represents the end stage of the natural history of this disease. It is also distinctly different from the congenital condition in which islands of gastric fundic epithelium are found in the upper half of the esophagus.

The definition of BE has evolved considerably over the past decade. Traditionally, BE was identified by the presence of columnar mucosa extending at least 3 cm into the esophagus. It is now recognized that the specialized, intestinal-type epithelium found in the Barrett’s mucosa is the only tissue predisposed to malignant degeneration. Consequently, the diagnosis of BE is presently made given any length of endoscopically identifiable columnar mucosa that proves, on biopsy, to show IM. Although long segments of columnar mucosa without IM do occur, they are uncommon and might be congenital in origin.

The hallmark of IM is the presence of intestinal goblet cells. There is a high prevalence of biopsy-demonstrated IM at the cardia, on the gastric side of the squamocolumnar junction, in the absence of endoscopic evidence of a CLE. Evidence is accumulating that these patches of what appears to be Barrett’s in the cardia have a similar malignant potential as in the longer segments, and are precursors for carcinoma of the cardia.

The long-term relief of symptoms remains the primary reason for performing antireflux surgery in patients with BE. Healing of esophageal mucosal injury and the prevention of disease progression are important secondary goals. In this regard, patients with BE are no different than the broader population of patients with gastroesophageal reflux. They should be considered for antireflux surgery when patient data suggest severe disease or predict the need for long-term medical management. Most patients with BE are symptomatic. Although it has been argued that some patients with BE may not have symptoms, careful history taking will reveal the presence of symptoms in most, if not all, patients.

Patients with BE have a spectrum of disease ranging from visually identifiable but short segments, to long segments of classic BE. In general, however, they represent a relatively severe stage of gastroesophageal reflux, usually with markedly increased esophageal acid exposure, deficient LES characteristics, poor esophageal body function, and a high prevalence of duodenogastroesophageal reflux. Gastric hypersecretion occurs in 44% of patients. Most will require long-term PPI therapy for relief of symptoms and control of coexistent esophageal mucosal injury. Given such profound deficits in esophageal physiology, antireflux surgery is an excellent means of long-term control of reflux symptoms for most patients with BE.

The typical complications in BE include ulceration in the columnar-lined segment, stricture formation, and a dysplasia-cancer sequence. Barrett’s ulceration is unlike the erosive ulceration of reflux esophagitis in that it more closely resembles peptic ulceration in the stomach or duodenum, and has the same propensity to bleed, penetrate, or perforate. Fortunately this complication occurs very rarely. The strictures found in BE occur at the squamocolumnar junction, and are typically higher than peptic strictures in the absence of BE. Ulceration and stricture in association with BE were commonly reported before 1975, but, with the advent of potent acid suppression medication, they have become less common. In contrast, the complication of adenocarcinoma developing in Barrett’s mucosa has become more common. Adenocarcinoma developing in Barrett’s mucosa was considered a rare tumor before 1975. Today, it occurs at approximately 0.2% to 0.5% per year of follow-up, which represents a risk 40 times that of the general population. Most, if not all, cases of adenocarcinoma of the esophagus arise in Barrett’s epithelium (Fig. 25-31). About one-third of all patients with BE present with malignancy.

The long-term risk of progression to dysplasia and adenocarcinoma, although not the driving force behind the decision to perform antireflux surgery, is a significant concern for both patient and physician. Although to date, there have been no prospective randomized studies documenting that antireflux surgery has an effect on the risk of progression to dysplasia and carcinoma, complete control of reflux of gastric juice into the esophagus is clearly a desirable goal.

**Respiratory Complications**

A significant proportion of patients with GERD will have associated respiratory symptoms. These patients may have laryngopharyngeal reflux-type symptoms, adult-onset asthma,
or even idiopathic pulmonary fibrosis. These symptoms and organ injury may occur in isolation or in conjunction with typical reflux symptoms such as heartburn and regurgitation. Several studies have demonstrated that up to 50% of patients with asthma have either endoscopically evident esophagitis or abnormal distal esophageal acid exposure. These findings support a causal relationship between GERD and aerodigestive symptoms and complications in a proportion of patients.

Etiology of Reflux-Induced Respiratory Symptoms. There are two mechanisms that have been proposed as the cause of reflux-induced respiratory symptoms. The reflux theory suggests that these symptoms are the direct result of laryngopharyngeal exposure and aspiration of gastric contents. The reflex theory suggests that the vagal-mediated afferent fibers result in bronchoconstriction during episodes of distal esophageal acidification. The evidence supporting a mechanism of direct exposure within the proximal esophagus is more frequently identified in patients with gastroesophageal reflux and respiratory symptoms than in patients who have gastroesophageal reflux symptoms alone. These findings are supported by scintigraphic studies, which have demonstrated aspiration of ingested radioisotope in patients with both gastroesophageal reflux and pulmonary symptoms. In animal studies, tracheal instillation of acid has been demonstrated to profoundly increase airway resistance. Finally, in patients who have undergone multichannel intraluminal impedance testing with a catheter configured to detect laryngopharyngeal reflux, a correlation between proximal fluid movement and laryngopharyngeal symptoms, such as cough, can be demonstrated.

The reflex mechanism is supported by the bronchoconstriction that occurs with the infusion of acid into the distal esophagus. There is a shared embryologic origin of the tracheoesophageal tract and vagus nerve, and this reflex is thought to be an afferent fiber-mediated reflex that protects the aerodigestive system from the aspiration of refluxate. In patients with respiratory symptoms and documented gastroesophageal reflux without proximal esophageal acid exposure, pulmonary symptoms will often times significantly improve or completely resolve.

after undergoing laparoscopic fundoplication. It is likely that both of the proposed mechanisms work simultaneously to cause these symptoms in the face of GERD.

The most difficult clinical challenge in formulating a treatment plan for reflux-associated respiratory symptoms resides in establishing the diagnosis. Although the diagnosis made be straightforward in patients with predominately typical reflux symptoms and secondary respiratory complaints, a substantial number of patients will have respiratory symptoms that dominate the clinical scenario. Typical gastroesophageal reflux symptoms, such as heartburn and regurgitation, may often be completely absent only to be uncovered with objective esophageal physiology testing. Traditionally, the diagnosis of reflux-induced respiratory injury is established using ambulatory dual probe pH monitoring, with one probe positioned within the distal esophagus and the other at a proximal location. Proximal probe positioning has included multiple locations such as the trachea, pharynx, and proximal esophagus. Although ambulatory esophageal pH monitoring allows a direct correlation between esophageal acidification and respiratory symptoms, sensitivity of this testing modality is poor, and the temporal relationship between laryngeal or pulmonary symptoms and reflux events is complex. In addition, as the refluxed gastric fluid travels proximally, it may be neutralized by saliva and therefore go undetected with pH monitoring. Impedance testing may also be used to detect the movement of fluid throughout the entire esophageal column regardless of pH content.

**Treatment.** Once the diagnosis is established, treatment may be initiated with either PPI therapy or antireflux surgery. A trial of high-dose PPI therapy may help establish the facts that reflux is partly or completely responsible for the respiratory symptoms. It is important to note that the persistence of symptoms in the face of aggressive PPI treatment does not necessarily rule out reflux as a possible cofactor or sole etiology.

Although there is probably some elements of a placebo effect, relief of respiratory symptoms can be anticipated in up to 50% of patients with reflux-induced asthma treated with antisecretory medications. However, when examined objectively, <15% of patients can be expected to have improvement in their pulmonary function with medical therapy. In properly selected patients, antireflux surgery improves respiratory symptoms in nearly 90% of children and 70% of adults with asthma and reflux disease. Improvements in pulmonary function can be demonstrated in around 30% of patients. Uncontrolled studies of the two forms of therapy (PPI and surgery) and the evidence from the two randomized controlled trials of medical vs. surgical therapy indicate that surgical valve reconstruction is the most effective therapy for reflux-induced asthma. The superiority of the surgery over PPI is most noticeable in the supine position, which corresponds with the nadir of PPI blood levels and resultant acid breakthrough and is the time in the circadian cycle when asthma symptoms are at their worst.

In asthmatic patients with an esophageal motility disorder, performing an antireflux operation will not prevent the regurgitation and possible aspiration of swallowed liquid or food "upstream" to the valve reconstruction. It is critical that esophageal body function be considered prior to surgical intervention in this patient population.

**Medical Therapy for Gastroesophageal Reflux Disease.** With the widespread availability of over-the-counter antisecretory medications, most patients with mild or moderate symptoms will carry self-medication. When initially identified with mild symptoms of uncomplicated GERD, patients can be placed on 12 weeks of simple antacids before diagnostic testing is initiated. This approach may successfully and completely resolve the symptoms. Patients should be counseled to elevate the head of the bed; avoid tight-fitting clothing; eat small, frequent meals; avoid eating the nighttime meal immediately prior to bedtime; and avoid alcohol, coffee, chocolate, and peppermint, which are known to reduce resting LES pressure and may aggravate symptoms.

Used in combination with simple antacids, algic acid may augment the relief of symptoms by creating a physical barrier to reflux, as well as by acid reduction. Algic acid reacts with sodium bicarbonate in the presence of saliva to form a highly viscous solution that floats like a raft on the surface of the gastric contents. When reflux occurs, this protective layer is refluxed into the esophagus, and acts as a protective barrier against the noxious gastric contents. Medications to promote gastric emptying, such as metoclopramide or domperidone, are beneficial in early disease, but of little value in more severe disease.

In patients with persistent symptoms, the mainstay of medical therapy is acid suppression. High-dosage regimens of hydrogen potassium PPIs, such as omeprazole (up to 40 mg/d), can reduce gastric acidity by as much as 80% to 90%. This usually heals mild esophagitis. In severe esophagitis, healing may occur in only one-half of the patients. In patients who reflux a combination of gastric and duodenal juice, acid-suppression therapy may give relief of symptoms, while still allowing mixed reflux to occur. This can allow persistent mucosal damage in an asymptomatic patient. Unfortunately, within 6 months of discontinuation of any form of medical therapy for GERD, 80% of patients have a recurrence of symptoms.

Once initiated, most patients with GERD will require lifelong treatment with PPIs, both to relieve symptoms and control any coexistent esophagitis or stricture. Although control of symptoms has historically served as the endpoint of therapy, the wisdom of this approach has recently been questioned, particularly in patients with BE. Evidence suggesting that reflux control may prevent the development of adenocarcinoma and lead to regression of dysplastic and nondysplastic Barrett’s segments has led many to consider control of reflux, and not symptom control, a better therapeutic endpoint. However, this hypothesis remains controversial. It should be noted that complete control of reflux using PPIs can be difficult, as has been highlighted by studies of acid breakthrough while on PPI therapy, and of persistent reflux following antireflux surgery. Castell, Triadafilopoulos, and others have shown that 40% to 80% of patients with BE continue to have abnormal esophageal acid exposure despite up to 20 mg twice daily of PPIs. Ablation trials have shown that mean doses of 56 mg of omeprazole were necessary to normalize 24-hour esophageal pH studies. It is likely that antireflux surgery results in more reproducible and reliable elimination of reflux of both acid and duodenal contents, although long-term outcome studies suggest that as many as 25% of postfundoplication patients will have persistent pathologic esophageal acid exposure confirmed by positive 24-hour pH studies.

**Suggested Therapeutic Approach.** Traditionally a stepwise approach is used for the treatment of GERD. First-line therapy entails antisecretory medication, usually PPIs, in most patients. Failure of medication, or the immediate return of symptoms after stopping treatment, suggests either that the patient may
have relatively severe disease or a non-GERD cause for his or her symptoms. Endoscopic examination at this stage of the patient's evaluation is recommended and will provide the opportunity to assess the degree of mucosal injury and presence of BE. Treatment options for these patients entails either long term PPI use vs. antireflux surgery. Laparoscopic antireflux surgery in these patients achieves long-term control of symptoms in 85% to 90%. The measurement of esophageal acid exposure via 24-hour pH should be undertaken when patients are considered for surgery. The status of the LES and esophageal body function with esophageal manometry should also be performed at this stage. These studies will serve to establish the diagnosis and assess esophageal body dysfunction.

**Surgical Therapy for Gastroesophageal Reflux Disease**

**Selection of Patients for Surgery.** Studies of the natural history of GERD indicate that most patients have a relatively benign form of the disease that is responsive to lifestyle changes and dietary and medical therapy, and do not need surgical treatment. Approximately 25% to 50% of the patients with GERD have persistent or progressive disease, and it is this patient population that is best suited to surgical therapy. In the past, the presence of esophagitis and a structurally defective LES was the primary indications for surgical treatment, and many internists and surgeons were reluctant to recommend operative procedures in their absence. However, one should not be deterred from considering antireflux surgery in a symptomatic patient with or without esophagitis or a defective sphincter, provided the disease process has been objectively documented by 24-hour pH monitoring. This is particularly true in patients who have become dependent upon therapy with PPIs, or require increasing doses to control their symptoms. It is important to note that a good response to medical therapy in this group of patients predicts an excellent outcome following antireflux surgery. In general, the key indications for antireflux surgery are (a) objectively proven gastroesophageal reflux disease, and (b) typical symptoms of gastroesophageal reflux disease (heartburn and/or regurgitation) despite adequate medical management, or (c) a younger patient unwilling to take lifelong medication. In addition, a structurally defective LES can also predict which patients are more likely to fail with medical therapy. Patients with normal sphincter pressures tend to remain well controlled with medical therapy, whereas patients with a structurally defective LES may not respond as well to medical therapy, and often develop recurrent symptoms within 1 to 2 years of beginning therapy. Such patients should be considered for an antireflux operation, regardless of the presence or absence of endoscopic esophagitis.

Young patients with documented reflux disease with or without a defective LES are also excellent candidates for antireflux surgery. They usually will require long-term medical therapy for control of their symptoms, and some will go on to develop complications of the disease. An analysis of the cost of therapy based on data from the Veterans Administration Cooperative trial indicates that surgery has a cost advantage over medical therapy in patients <49 years of age.

Severe esophageal esophagitis in a symptomatic patient with a structurally defective LES is also an indication for early surgical therapy. These patients are prone to breakthrough of their symptoms while receiving medical therapy. Symptoms and mucosal injury can be controlled in such patients, but careful monitoring is required, and increasing dosages of PPIs are necessary. In everyday clinical practice, however, such treatment can be both difficult and impractical, and, in such cases, antireflux surgery can be considered early, especially if PPI therapy is problematic.

The development of a stricture in a patient represents a failure of medical therapy, and is also an indication for a surgical antireflux procedure. In addition, strictures are often associated with a structurally defective sphincter and loss of esophageal contractility. Before proceeding with surgical treatment, malignancy and a drug-related etiology of the stricture should be excluded, and the stricture progressively dilated up to a 50 to 60F bougie. When the stricture is fully dilated, the relief of dysphagia is evaluated and esophageal manometry is performed to determine the adequacy of peristalsis in the distal esophagus. If dysphagia is relieved and the amplitude of esophageal contractions is adequate, an antireflux procedure should be performed; if there is a global loss of esophageal contractility, caution should be exercised in performing an antireflux procedure with a complete fundoplication, and a partial fundoplication should be considered.

Barrett’s CLE is commonly associated with a severe structural defect of the LES and often poor contractility of the esophageal body. Patients with BE are at risk of the development of an adenocarcinoma. Whilst surgeons would like to think that an antireflux procedure can reduce the risk of progression to cancer, the evidence supporting this is relatively weak, and for now Barrett’s esophagus should be considered to be evidence that the patient has gastroesophageal reflux, and progression to antireflux surgery is indicated for the treatment of reflux symptoms, not cancer progression. If, however, high grade dysplasia or intramucosal carcinoma is found on mucosal biopsy specimens, treatment should then be directed at the BE and the lesion, using either evaluation endoscopic ablation, endoscopic resection or esophageal resection.

The majority of patients requiring treatment for reflux have a relatively mild form of disease and will respond to antisecretory medications. Patients with more severe forms of disease, particularly those who develop persistent or progressive disease, should be considered for definitive therapy. Laparoscopic fundoplication will provide a long-term cure in the majority of these patients, with minimal discomfort and an early return to normal activity.

**Preoperative Evaluation.** Before proceeding with an antireflux operation, several factors should be evaluated. The clinical symptoms should be consistent with the diagnosis of gastroesophageal reflux. Patients presenting with the typical symptoms of heartburn and/or regurgitation which have responded, at least partly, to PPI therapy, will generally do well following surgery, whereas patients with atypical symptoms have a less predictable response. Reflux should also be objectively confirmed by either the presence of ulcerative esophagitis or an abnormal 24 hour pH study.

The propulsive force of the body of the esophagus should be evaluated by esophageal manometry to determine if it has sufficient power to propel a bolus of food through a newly reconstructed valve. Patients with normal peristaltic contractions can be considered for a 360° Nissen fundoplication or a partial fundoplication, depending on patient and surgeon preferences. When peristalsis is absent a partial fundoplication is probably the procedure of choice, but only if achalasia has been ruled out.
Hiatal anatomy should also be assessed. In patients with smaller hiatal hernias endoscopy evaluation usually provides sufficient information. However, when patients present with a very large hiatus hernia or for revision surgery after previous antireflux surgery, contrast radiology provides better anatomical information. The concept of anatomic shortening of the esophagus is controversial, with divergent opinions held about how common this problem is. Believers claim that anatomic shortening of the esophagus compromises the ability of the surgeon to perform an adequate repair without tension, and that this can lead to an increased incidence of breakdown or thoracic displacement of the repair. Some of those that hold this view claim that esophageal shortening is present when a barium swallow X-ray identifies a sliding hiatal hernia that will not reduce in the upright position, or that measures more than 5 cm in length at endoscopy. When identified these surgeons usually undertake a gastroplasty to the antireflux procedure. Others claim that esophageal shortening is overdiagnosed and rarely seen, and that the morbidity of adding a gastroplasty outweighs any benefits. These surgeons would recommend a standard antireflux procedure in all patients undergoing primary surgery.

**Principles of Surgical Therapy.** The primary goal of antireflux surgery is to safely create a new antireflux valve at the gastroesophageal junction, while preserving the patient’s ability to swallow normally and to belch to relieve gaseous distention. Regardless of the choice of the procedure, this goal can be achieved if attention is paid to some basic principles when reconstructing the antireflux mechanism. First, the operation should create a flap valve which prevents regurgitation of gastric contents into the esophagus. This will result in an increase in the pressure of the distal esophageal sphincter region. Following a Nissen fundoplication the expected increase is to a level twice the resting gastric pressure (i.e., 12 mmHg for a gastric pressure of 6 mmHg). The extent of the pressure rise is often less following a partial fundoplication, although with all types of fundoplication the length of the reconstructed valve should be at least 3 cm. This not only augments sphincter characteristics in patients in whom they are reduced before surgery, but prevents unfolding of a normal sphincter in response to gastric distention (Fig. 25-32). Preoperative and postoperative esophageal manometry measurements have shown that the resting sphincter pressure and the overall sphincter length can be surgically augmented over preoperative values, and that the change in the former is a function of the degree of gastric wrap around the esophagus (Fig. 25-33). However, the aim of any fundoplication is to create a loose wrap, and to maintain the position of the gastric fundus close to the distal intra-abdominal esophagus, in a flap valve arrangement. The efficacy of this relies on the close relationship between the fundus and the esophagus, not the “tightness” of the wrap.

Second, the operation should place an adequate length of the distal esophageal sphincter in the positive-pressure environment of the abdomen by a method that ensures its response to changes in intra-abdominal pressure. The permanent restoration of 2 or more cm of abdominal esophagus ensures the preservation of the relationship between the fundus and the esophagus. All of the popular antireflux procedures increase the length of the sphincter exposed to abdominal pressure by an average of at least 1 cm.

Third, the operation should allow the reconstructed cardia to relax on deglutition. In normal swallowing, a vagally mediated relaxation of the distal esophageal sphincter and the gastric fundus occurs. The relaxation lasts for approximately 10 seconds and is followed by a rapid recovery to the former tone. To ensure relaxation of the sphincter, three factors are important: (a) Only the fundus of the stomach should be used to buttress the sphincter, because it is known to relax in concert with the sphincter; (b) the gastric wrap should be properly placed around the sphincter and not incorporate a portion of the stomach or be placed around the stomach itself, because the body of the stomach does not relax with swallowing; and (c) damage to the vagal nerves during dissection of the thoracic esophagus should be avoided because it may result in failure of the sphincter to relax.

Fourth, the fundoplication should not increase the resistance of the relaxed sphincter to a level that exceeds the peristaltic power of the body of the esophagus. The resistance of the relaxed sphincter depends on the degree, length, and diameter of the gastric fundic wrap, and on the variation in intra-abdominal pressure. A 360° gastric wrap should be no longer than 2 cm and constructed over a large (50 to 60F) bougie. This will ensure that the relaxed sphincter will have an adequate diameter with

---

**Figure 25-32.** A graphic illustration of the shortening of the lower esophageal sphincter that occurs as the sphincter is “taken up” by the cardia as the stomach distends.
minimal resistance. A bougie is not necessary when constructing a partial wrap.

Fifth, the operation should ensure that the fundoplication can be placed in the abdomen without undue tension, and maintained there by approximating the crura of the diaphragm above the repair. Leaving the fundoplication in the thorax converts a sliding hernia into a PEH, with all the complications associated with that condition. Maintaining the repair in the abdomen under tension predisposes to an increased incidence of recurrence. How common this problem is encountered is disputed, with some surgeons advocating lengthening the esophagus by gastroplasty and constructing a partial fundoplication, and others claiming that this issue is now rarely encountered.

Procedure Selection. A laparoscopic approach is now used routinely in all patients undergoing primary antireflux surgery. Some surgeons advocate the use of a single antireflux procedure for all patients, whereas others advocate a tailored approach. Advocates of the laparoscopic Nissen fundoplication as the procedure of choice for a primary antireflux repair would generally apply this procedure in all patients with normal or near normal esophageal motility, and reserve a partial fundoplication for use in individuals with poor esophageal body motility. Others, based on the good longer term outcomes now reported following partial fundoplication procedures, advocate the routine application of a partial fundoplication procedure, thereby avoiding any concerns about constructing a fundoplication in individuals with poor esophageal motility.

Experience and randomized studies have shown that both the Nissen fundoplication and various partial fundoplication procedures are all effective and durable antireflux repairs, and generate an excellent outcome in approximately 90% of patients at longer term follow-up.

Primary Antireflux Repairs

Nissen Fundoplication. The most common antireflux procedure is the Nissen fundoplication. In the past this procedure has been performed through an open abdominal or a chest incision, but with the development of laparoscopic approaches primary antireflux surgery is now routinely undertaken using the laparoscope. Rudolph Nissen described this procedure as a 360° fundoplication around the lower esophagus for a distance of 4 to 5 cm, without division of the short gastric blood vessels. Although this provided good control of reflux, it was associated with a number of side effects that have encouraged modifications of the procedure as originally described. These include using only the gastric fundus to envelop the esophagus in a fashion analogous to a Witzel jejunostomy, sizing the fundoplication with a large (50 to 60F) bougie, limiting the length of the fundoplication to 1 to 2 cm, and dividing the short gastric vessels. The essential elements necessary for the performance of a trans-abdominal fundoplication are common to both the laparoscopic and open procedures and include the following:

1. Hiatal dissection and preservation of both vagi along their entire length
2. Circumferential esophageal mobilization
3. Hiatal closure, usually posterior to the esophagus
4. Creation of a short and floppy fundoplication over an esophageal dilator

In addition, many surgeons also routinely divide the short gastric blood vessels, although this step is not universally applied, and the results of several randomized trials have failed to show that this step yields any benefit.

The laparoscopic approach to fundoplication has now replaced the open abdominal Nissen fundoplication as the procedure of choice. Five ports are usually used (Fig. 25-34), and dissection is begun by incising the gastrohepatic omentum above and below the hepatic branch of the anterior vagus nerve, which is usually preserved. The circumference of the diaphragmatic hiatus is dissected and the esophagus is mobilized by careful dissection of the anterior and posterior soft tissues within the hiatus. The esophagus is held anterior and to the left and the hiatal pillars are approximated with interrupted non-absorbable sutures, starting posteriorly and working anteriorly. A tension-free fundoplication should be constructed. This can usually be achieved either with or without division of the short gastric blood vessels, according to surgeon preference. If the vessels are divided, the upper one third of the greater curvature is mobilized by sequentially dissecting and divided these vessels, commencing distally and working proximally. Following complete fundal mobilization,
the posterior wall of the fundus is brought behind the esophagus to the right side, and the anterior wall of the fundus is brought anterior to the esophagus. The fundic lips are manipulated to allow the fundus to envelop the esophagus without twisting. A 50 to 60F bougie is passed to properly size the fundoplication, and it is sutured using non-absorbable sutures. Some surgeons use a single U-stitch of 2-0 polypropylene buttressed with felt pledgets (Fig. 25-35), and others use 2-4 interrupted sutures.

**Posterior Partial Fundoplication.** Partial fundoplications were developed as an alternative to the Nissen procedure in an attempt to minimize the risk of postfundoplication side effects, such as dysphagia, inability to belch, and flatulence. The commonest approach has been a posterior partial or Toupet fundoplication. Some surgeons use this type of procedure for all patients presenting for antireflux surgery, whereas others apply a tailored approach in which a partial fundoplication is

---

**Figure 25-35.** A. Laparoscopic Nissen fundoplication is performed with a five-trocar technique. B. The liver retractor is affixed to a mechanical arm to hold it in place throughout the operation. C. After division of the gastrohepatic omentum above the hepatic branch of the vagus (pars flaccida), the surgeon places a blunt atraumatic grasper beneath the phrenoesophageal ligament. D. After completion of the crural closure, an atraumatic grasper is placed right to left behind the gastroesophageal junction. The grasper is withdrawn, pulling the posterior aspect of the gastric fundus behind the esophagus. E. Once the suture positions are chosen, the first stitch (2-0 silk, 20 cm long) is introduced through the 10-mm trocar, and the needle is passed first through the left limb of the fundus, then the esophagus (2.5 cm above the gastroesophageal junction), then through the right limb of the fundus. F. Final position of the fundoplication. (Illustration continued on next page.)
constructed in patients with impaired esophageal motility, in which the propulsive force of the esophagus is thought to be insufficient to overcome the outflow obstruction of a complete fundoplication. The Toupet posterior partial fundoplication consists of a 270° gastric fundoplication around the distal 4 cm of esophagus (Fig. 25-36). It is usually stabilized by anchoring the wrap posteriorly to the hiatal rim.

**Anterior Partial Fundoplication.** An alternative approach to partial fundoplication is to construct an anterior partial fundoplication. Following posterior hiatal repair, the anterior fundus is rolled over the front of the esophagus and sutured to the hiatal rim and the esophageal wall. Division of the short gastric vessels is never needed when constructing this type of fundoplication. Various degrees of anterior partial fundoplication have been described—90°, 120°, 180°. The anterior 180° partial fundoplication (Fig. 25-37) provides a more robust fundoplication and achieves an excellent longer term outcome in approximately 90% of patients at follow-up of at least 10 years. With this procedure the fundus and esophagus are sutured to the right side of the hiatal rim to create a flap valve at the gastroesophageal junction, and to stabilize a 3-4 cm length of intra-abdominal esophagus.
Collis Gastroplasty. When a shortened esophagus is encountered, many surgeons choose to add an esophageal lengthening procedure before fundoplication, to reduce the tension on the gastro-esophageal junction, believing this will minimize the risk of failure due to postoperative hiatus hernia. The commonest approach to this is the Collis gastroplasty. This entails using a stapler to divide the cardia and upper stomach, parallel to the lesser curvature of the stomach, thereby creating a gastric tube in continuity with the esophagus, and effectively lengthening the esophagus by several centimeters. Laparoscopic techniques for Collis gastroplasty have been described (Fig. 25-38). Following gastroplasty a fundoplication is constructed, with the highest suture is placed on the native esophagus when constructing a Nissen fundoplication. Not all surgeons choose to undertake a Collis procedure, however, as there is controversy about the actual incidence of the shortened esophagus and widely divergent views are held about how often this problem is encountered. In addition, some surgeons have questioned the wisdom of creating an amotile tube of gastric wall, which can secrete acid, and then placing a Nissen fundoplication below this.

Outcome after Fundoplication. Studies of long-term outcome following both open and laparoscopic fundoplication document the ability of laparoscopic fundoplication to relieve typical reflux symptoms (heartburn, regurgitation, and dysphagia) in more than 90% of patients at follow-up intervals averaging 2 to 3 years and 80% to 90% of patients 5 years or more following surgery. This includes evidence-based reviews of antireflux surgery, prospective randomized trials comparing antireflux surgery to PPI therapy and open to laparoscopic

Figure 25-38. A. After removal of the fat pad and release of tension on the Penrose drain, the gastroesophageal junction (GES) retracts to the level of the hiatus. The interior end of the staple line is marked 2.5 cm below the angle of His. B. The first horizontal firing of the stapler occurs by maximally articulating the stapler to the left, aiming toward the previously marked spot adjacent to the dilator. C. The vertical staple line is created by a single firing of the GIA placed parallel and flush against the 48F dilator. D. The highest Nissen fundoplication suture is placed on the native esophagus, and the second suture tucks in the apex of the staple line.
fundoplication and analysis of U.S. national trends in use and outcomes. Postoperative pH studies indicate that more than 90% of patients will normalize their pH tracings. The results of laparoscopic fundoplication compare favorably with those of the “modern” era of open fundoplication. They also indicate the less predictable outcome of atypical reflux symptoms (cough, asthma, laryngitis) after surgery, being relieved in only two-thirds of patients.

The goal of surgical treatment for GERD is to relieve the symptoms of reflux by re-establishing the gastroesophageal barrier. The challenge is to accomplish this without inducing dysphagia or other untoward side effects. Dysphagia, existing before surgery, usually improves following laparoscopic fundoplication. Temporary dysphagia is common after surgery and generally resolves within 3 months, but can take up to 12 months in some individuals, and dysphagia sufficient to require ongoing dietary modification persists in up to 5% of individuals following Nissen fundoplication. Other side effects common to antireflux surgery include the inability to belch and vomit and increased flatulence. Most patients cannot vomit through an intact wrap, though this is rarely clinically relevant. Most patients are unable to belch gas from the stomach in the first 3 to 6 months after fundoplication, but 80%–90% regain the ability to belch normally beyond the first 12 months follow-up. Hyperflatulence is a common and noticeable problem, likely related to increased air swallowing that is present in most patients with reflux disease, aggravated by the inability to belch in some patients.

Randomized Controlled Trials Addressing Surgical Technique

Division of the Short Gastric Blood Vessels Originally, Nissen’s description of a total fundoplication entailed a 360° fundoplication during which the short gastric blood vessels were left intact. However, with reports of troublesome post-operative dysphagia division of these vessels, to achieve full fundal mobilization and thereby ensure a loose fundoplication, was promoted and has entered common practice. The evidence supporting dividing these vessels has been based on the outcomes from uncontrolled case series of patients undergoing Nissen fundoplication either with or without division of the short gastric vessels. However, the results from these studies have been conflicting with different proponents reporting good results irrespective of whether these vessels have been divided or not. To address this issue 6 randomized trials which enrolled a total of 438 patients have been reported. None of these trials demonstrated any differences for the postoperative dysphagia or recurrent gastro-esophageal reflux. However, in the 3 largest of the 6 trials an increased incidence of flatulence and bloating symptoms, as well as greater difficulty with belching, was seen in patients in whom the short gastric vessels were divided.

A recent meta-analysis from Engstrom et al, generated by combining the raw data from Australian and Swedish trials, evaluated a larger cohort of 201 patients, with 12 years follow-up in 170, and also confirmed equivalent reflux control, but more abdominal bloating after division of the short gastric vessels. Overall, these trials fail to support the belief that dividing the short gastric vessels improves any outcome following Nissen fundoplication. The trials actually suggest that dividing the vessels increases the complexity of the procedure, and leads to a poorer outcome due to the increase in bloating symptoms.

Nissen vs. Posterior Partial Fundoplication Eleven randomized trials have compared Nissen vs. posterior partial fundoplication. Some of the trials were relatively small and underpowered, so contribute little to the pool of evidence as they are either small or underpowered, and failed to show significant outcome differences. The larger trials, however, have consistently demonstrated equivalent reflux control, but a reduced incidence of wind related side-effects (flatulence, bloating, and inability to belch) following posterior partial fundoplication procedures, although less dysphagia following a posterior fundoplication was only demonstrated in 2 of the 11 trials. Lundell et al reported the outcomes of Nissen vs. Toupet partial fundoplication in a trial which enrolled 137 patients with reported follow-up to 18 years. Reflux control and dysphagia symptoms were similar, but flatulence was commoner after Nissen fundoplication at some medium-term follow-up time points and revision surgery was more common following Nissen fundoplication, mainly to correct postoperative paraesophageal herniation. At 18 years follow-up, success rates of more than 80% were reported for both procedures, as well as no significant differences in the incidence of side effects. The data from this trial suggested that the mechanical side effects following Nissen fundoplication progressively improve with very long term follow-up. Strate et al reported 2 year follow-up in a trial that enrolled 200 patients. Approximately 85% of each group was satisfied with the clinical outcome, but dysphagia was significantly more common following Nissen fundoplication (19 vs. 8 patients).

Other trials (Guérin et al–140 patients, Booth et al–127, Khan et al–121, Shaw et al–100) also report similar reflux control within the first few years of follow-up. Only Booth et al demonstrated less dysphagia following posterior fundoplication. Subgroup analysis in 3 trials (Booth, Shaw, Zornig) did not reveal differences between patients with vs. without poor preoperative oesophageal motility. Overall these trials suggest that some side-effects, mainly wind-related issues, are less common following posterior partial fundoplication. However, the hypothesis that dysphagia is less of a problem following posterior partial fundoplication has only been substantiated in 2 of 11 trials.

Nissen vs. Anterior Fundoplication Six trials have evaluated Nissen vs. anterior partial fundoplication variants. Four have assessed Nissen vs. anterior 180° partial fundoplication (Watson et al–107 patients, Baigrie et al–161, Cao et al–100, Raue et al–64). These trials all demonstrated equivalent reflux control, but less dysphagia and less wind-related side effects after anterior 180° partial fundoplication at up to 5 years follow-up. Only the study from Watson et al has reported follow-up to 10 years, and at late follow-up in their trial there were no significant outcome differences for the 2 procedures, with equivalent control of reflux, and no differences for side effects due to a progressive decline in dysphagia as follow-up extended beyond 5 years.

Two trials compared laparoscopic anterior 90° partial fundoplication vs. Nissen fundoplication (Watson et al–112 patients, Spence et al–79). In both of these trials side-effects were less common following anterior 90° fundoplication, but this was offset by a slightly higher incidence of recurrent reflux at up to 5 years follow-up. Satisfaction with the overall outcome was similar for both fundoplication variants.

Anterior vs. posterior partial fundoplication Two randomized trials have directly compared anterior vs. posterior partial fundoplication. Hagedorn et al randomized 95 patients to undergo either Toupet vs. anterior 120° partial fundoplication, and Khan et al enrolled 103 patients to anterior 180° vs.
posterior partial fundoplication. Both studies demonstrated better reflux control, offset by more side effects following posterior partial fundoplication. The anterior 120° partial fundoplication performed by Hagedorn et al was similar to the anterior 90° variant described above. However, the outcomes following this procedure were much worse in this trial than the outcomes in other studies, with the average exposure time to acid (pH < 4%–5.6%) following anterior fundoplication in their study unusually high compared to other studies. Khan et al only reported 6 months follow-up and longer term outcomes are awaited before drawing firm conclusions. The overall results from all 8 trials which included an anterior fundoplication variant suggests that this type of fundoplication achieves satisfactory reflux control, with less dysphagia and other side-effects, yielding a good overall outcome. However, the reduced incidence of troublesome side-effects is traded off against a higher risk of recurrent reflux.

**Outcome of Antireflux Surgery in Patients with Barrett’s Esophagus.** Few studies have focused on the alleviation of symptoms after antireflux surgery in patients with BE (Table 25-7). Those that are available document excellent to good results in 72% to 95% of patients at 5 years following surgery. Several non-randomized studies have compared medical and surgical therapy and report better outcomes after antireflux surgery. Parrilla and colleagues reported the only randomized trial to evaluate this issue. They enrolled 101 patients over 18 years (1982 to 2000), and median follow-up was 6 years. Medical therapy consisted of 20 mg of omeprazole (PPI) twice daily since 1992 in all medically treated patients, and surgical therapy consisted of an open Nissen fundoplication. The symptomatic outcome in the two groups was nearly identical, although esophagitis and/or stricture persisted in 20% of the medically treated patients, compared to only 3% to 7% of patients following antireflux surgery. About 15% of patients had abnormal acid exposure after surgery. Although pH data were not routinely collected in patients on PPI therapy, in the subgroup of 12 patients that did have 24-hour monitoring on treatment, 3 of 12 (25%) had persistently high esophageal acid exposure, and most (75%) had persistently high bilirubin exposure.

The common belief that Barrett’s epithelium cannot be reversed by antireflux surgery is may not be correct. Within the control arm of a randomized trial of ablation vs. surveillance, Bright and associates identified approximately 50% regression in the length of Barrett’s esophagus in 20 patients within the control arm of a randomized trial of ablation vs. surveillance. Current data indicate that patients with BE should remain in an endoscopic surveillance program following antireflux surgery. Biopsy specimens should be reviewed by a pathologist with expertise in the field. If low-grade dysplasia is confirmed, biopsy specimens should be repeated after 12 weeks of high-dose acid suppression therapy. If high-grade dysplasia or intramucosal cancer is evident on more than one biopsy specimen, then treatment is escalated. Treatment options include endoscopic mucosal resection, endoscopic ablation of the BE, or esophageal resection. Esophageal resection is advisable when an invasive cancer (stage T1b or deeper) is present, or for multifocal long segment BE in younger and fit patients in whom endoscopic treatments are unlikely to be adequate. Endoscopic mucosal resection allows smaller intramucosal tumors to be removed with clear pathology margins, and it can be used as a “big biopsy” to obtain better pathological staging, and even to excise shorter segments of BE in a piecemeal fashion. Ablation, commonly using radiofrequency ablation, has been shown at short term follow-up in a randomized trial to reduce the rate of progression from high grade dysplasia to invasive cancer by approximately 50%. However, following any endoscopic treatment patients need to continue with close endoscopic surveillance as recurrence can occur and the longer term outcome following these treatments remains uncertain. Early detection and treatment have been shown to decrease the mortality rate from esophageal cancer in these patients.

If the dysplasia is reported as lower grade or indeterminant, then inflammatory change that is often confused with dysplasia should be suppressed by a course of acid suppression therapy in high doses for 2 to 3 months, followed by re biopsy of the Barrett’s segment.

**Reoperation for Failed Antireflux Repairs.** Failure of an antireflux procedure occurs when, after the repair, the patient is unable to swallow normally, experiences upper abdominal discomfort during and after meals, or has recurrence or persistence of reflux symptoms. The assessment of these symptoms and the selection of patients who need further surgery are challenging problems. Functional assessment of patients who have recurrent, persistent, or emergent new symptoms following a primary antireflux repair is critical to identifying the cause of the failure. Analysis of patients requiring reoperation after a previous antireflux procedure shows that placement of the wrap around the stomach is the most frequent cause for failure after open procedures, while herniation of the repair into the chest is the most frequent cause of failure after a laparoscopic procedure. Partial or complete breakdown of the fundoplication and construction of a too-tight a fundoplication or over narrowing the esophageal hiatus occurs with both open and closed procedures.

Patients who have recurrence of heartburn and regurgitation without dysphagia and have good esophageal motility are most amenable to reoperation, and can be expected to have an excellent outcome. When dysphagia is the cause of failure, the situation can be more difficult to manage. If the dysphagia occurred immediately following the repair, it is usually due to a technical failure, most commonly a misplaced fundoplication around the upper stomach, or over-narrowing of the esophageal diaphragmatic hiatus and reoperation is usually satisfactory. When dysphagia is associated with poor motility and multiple previous repairs, further revision fundoplication is unlikely to be successful and in otherwise fit patients it is appropriate to seriously consider esophageal resection. With each reoperation the esophagus is damaged further, and the chances of preserving function become less. Also, blood supply is reduced, and ischemic necrosis of the esophagus can occur after several previous mobilizations.

GIANT DIAPHRAGMATIC (HIATAL) HERNIAS

With the advent of clinical radiology, it became evident that a diaphragmatic hernia was a relatively common abnormality and was not always accompanied by symptoms. Three types of esophageal hiatal hernia were identified: (a) the sliding hernia, type I, characterized by an upward dislocation of the cardia in the posterior mediastinum (Fig. 25-39A); (b) the rolling or PEH, type II, characterized by an upward dislocation of the gastric fundus alongside a normally positioned cardia (Fig. 25-39B); and (c) the combined sliding-rolling or mixed hernia, type III, characterized by an upward dislocation of both the cardia and the gastric fundus (Fig. 25-39C). The end stage of type I and type II hernias occurs when the whole stomach migrates up into the chest by rotating 180° around its longitudinal axis, with the cardia and pylorus as fixed points. In this situation the abnormality is usually referred to as an intrathoracic stomach (Fig. 25-39D). In some taxonomies, a type IV hiatal hernia is declared when an additional organ, usually the colon, herniates as well. Type II-IV hiatal hernias are also referred to as paraesophageal hernia (PEH), as a portion of the stomach is situated adjacent to the esophagus, above the gastroesophageal junction.

Incidence and Etiology

The true incidence of a hiatal hernia is difficult to determine because of the absence of symptoms in a large number of patients who are subsequently shown to have a hernia. When radiographic

Figure 25-39. A. Radiogram of a type I (sliding) hiatal hernia. B. Radiogram of a type II (rolling or paraesophageal) hernia. C. Radiogram of a type III (combined sliding-rolling or mixed) hernia. D. Radiogram of an intrathoracic stomach. This is the end stage of a large hiatal hernia regardless of its initial classification. Note that the stomach has rotated 180° around its longitudinal axis, with the cardia and pylorus as fixed points. (Reproduced with permission from DeMeester TR, Bonavina L: Paraesophageal hiatal hernia, in Nyhus LM, Condon RE (eds): Hernia, 3rd ed. Philadelphia: Lippincott, 1989, p 684.)
Examinations are done in response to GI symptoms, the incidence of a sliding hiatal hernia is seven times higher than that of a PEH. The PEH is also known as the giant hiatal hernia. Over time the pressure gradient between the abdomen and chest enlarges the hiatal hernia. In many cases the type 1 sliding hernia will evolve into a type III mixed hernia. Type II hernias are quite rare.

The age distribution of patients with PEHs is significantly different from that observed in sliding hiatal hernias. The median age of the former is 61 years old; of the latter, 48 years old. PEHs are more likely to occur in women by a ratio of 4:1.

Structural deterioration of the phrenoesophageal membrane over time may explain the higher incidence of hiatal hernias in the older age group. These changes involve thinning of the upper fascial layer of the phrenoesophageal membrane (i.e., the supradiaphragmatic continuation of the endothoracic fascia) and loss of elasticity in the lower fascial layer (i.e., the infra-diaphragmatic continuation of the transversalis fascia). Consequently, the phrenoesophageal membrane yields to stretching in the cranial direction due to the persistent intra-abdominal pressure and the tug of esophageal shortening on swallowing. Interestingly, the stretching and thinning occurs more anteriorly and posteriorly, with fixation of the left crus of the diaphragm to the stomach at the 3 o’clock position, as viewed from the foot. This creates an anterior and posterior hernia sac, the latter of which is often filled with epiphenic and retroperitoneal fat. These observations point to the conclusion that the development of a hiatal hernia is an age-related phenomenon secondary to repetitive upward stretching of the phrenoesophageal membrane.

**Clinical Manifestations**

The clinical presentation of a giant hiatal (paraesophageal) hernia differs from that of a sliding hernia. There is usually a higher prevalence of symptoms of dysphagia and postprandial fullness with PEHs, but the typical symptoms of heartburn and regurgitation present in sliding hiatal hernias can also occur. Both are caused by gastroesophageal reflux secondary to an underlying mechanical deficiency of the cardia. The symptoms of dysphagia and postprandial fullness in patients with a PEH are explained by the compression of the adjacent esophagus by a distended cardia, or twisting of the GEJ by the torsion of the stomach that occurs as it becomes progressively displaced in the chest. The postprandial fullness or retrosternal chest pain is thought to be a result of distension of the stomach with gas or food in the hiatal hernia. Many patients with sliding hernias and reflux symptoms will lose the reflux symptoms when the hernia evolves into the paraesophageal variety. This can be explained by the re-creation of the cardiophrenic angle when the stomach herniates alongside the GEJ or becomes twisted in the sac. Repair of the hernia without addressing the reflux can create extremely bothersome heartburn. Respiratory complications are frequently associated with a PEH, and consist of dyspnea and recurrent pneumonia from aspiration. New research demonstrates that the cause of dyspnea in the presence of a giant PEH is more likely to be left atrial compression, decreasing cardiac output, than a restrictive pulmonary effect, as has been hypothesized for many years.

Approximately one third of patients with a PEH are found to be anemic, which is due to recurrent bleeding from ulceration of the gastric mucosa in the herniated portion of the stomach, even if ulcerations are not detected at the time of endoscopy. The association of anemia and PEH is best proven by fixing the hernia. Anemia is corrected in >90% of patients with this condition. With time, more and more stomach migrates into the chest and can cause intermittent foregut obstruction due to the...
rotation that has occurred. In contrast, many patients with PEH are asymptomatic or complain of minor symptoms. However, the presence of a PEH can be life threatening in that the hernia can lead to sudden catastrophic events, such as excessive bleeding or volvulus with acute gastric obstruction or infarction. With mild dilatation of the stomach, the gastric blood supply can be markedly reduced, causing gastric ischemia, ulceration, perforation, and sepsis. The probability of incarceration/strangulation is not well known, although recent studies suggest that the lifetime risk is less than 5%, making this concern an insufficient concern for routine repair of the asymptomatic PEH.

The symptoms of sliding hiatal hernias are usually due to functional abnormalities associated with gastroesophageal reflux and include heartburn, regurgitation, and dysphagia. These patients have a mechanically defective LES, giving rise to the reflux of gastric juice into the esophagus and the symptoms of heartburn and regurgitation. The symptom of dysphagia occurs from the presence of mucosal edema, Schatzki’s ring, stricture, or the inability to organize peristaltic activity in the body of the esophagus as a consequence of the disease.

There is a group of patients with sliding hiatal hernias not associated with reflux disease who have dysphagia without any obvious endoscopic or manometric explanation. Video barium radiograms have shown that the cause of dysphagia in these patients is an obstruction of the swallowed bolus by diaphragmatic impingement on the herniated stomach. Manometrically, this is reflected by a double-humped high-pressure zone at the GEJ. The first pressure rise is due to diaphragmatic impingement on the herniated stomach, and the second to the true distal esophageal sphincter. These patients usually have a mechanically competent sphincter, but the impingement of the diaphragm on the stomach can result in propelling the contents of the supradiaphragmatic portion of the stomach up into the esophagus and pharynx, resulting in complaints of pharyngeal regurgitation and aspiration. Consequently, this abnormality is often confused with typical GERD. Surgical reduction of the hernia results in relief of the dysphagia in 91% of patients.

**Diagnosis**

A chest X ray with the patient in the upright position can diagnose a hiatal hernia if it shows an air-fluid level behind the cardiac shadow. This is usually caused by a PEH or an intrathoracic stomach. The accuracy of the upper GI barium study in detecting a paraesophageal hiatal hernia is greater than for a sliding hernia because the latter can often spontaneously reduce. The paraesophageal hiatal hernia is a permanent herniation of the stomach into the thoracic cavity, so a barium swallow provides the diagnosis in virtually every case. Attention should be focused on the position of the GEJ, when seen, to differentiate it from a type II hernia (see Fig. 25-39B and C). Fiber-optic esophagoscopy is useful in the diagnosis and classification of a hiatal hernia because the scope can be retroflexed. In this position, a sliding hiatal hernia can be identified by noting a gastric pouch lined with rugal folds extending above the impression caused by the crura of the diaphragm, or measuring at least 2 cm between the crura, identified by having the patient sniff, and the squamocolumnar junction on withdrawal of the scope (Fig. 25-40). A PEH is identified on retroversion of the scope by noting a separate orifice adjacent to the GEJ into which gastric rugal folds ascend. A sliding-rolling or mixed hernia can be identified by noting a gastric pouch lined with rugal folds above the diaphragm, with the GEJ entering about midway up the side of the pouch.

**Pathophysiology**

Physiologic testing with 24-hour esophageal pH monitoring has shown increased esophageal exposure to acid gastric juice in 60% of the patients with a paraesophageal hiatal hernia, compared with the observed 71% incidence in patients with a sliding hiatal hernia. It is now recognized that paraesophageal hiatal hernia can be associated with pathologic gastroesophageal reflux.

Physiologic studies have also shown that the competency of the cardia depends on an interrelationship between distal esophageal sphincter pressure, the length of the sphincter that is exposed to the positive-pressure environment of the abdomen, and the overall length of the sphincter. A deficiency in any one of these manometric characteristics of the sphincter is associated with incompetency of the cardia regardless of whether a hernia is present. Patients with a PEH who have an incompetent cardia have been shown to have a distal esophageal sphincter with normal pressure, but a shortened overall length and displacement outside the positive-pressure environment of the abdomen. One might expect esophageal body function to be diminished with the esophagus “accordioned” up into the chest. Surprisingly, esophageal peristalsis in patients with PEH is normal in 88%.

**Treatment**

The treatment of paraesophageal hiatal hernia is largely surgical. Controversial aspects include: (a) indications for repair, (b) diaphragmatic repair, (c) role of fundoplication, and (d) existence and treatment of the short esophagus.

**Indications and Surgical Approach.** The presence of a paraesophageal hiatal hernia has traditionally been considered an indication for surgical repair. This recommendation is largely
It has been shown that PEH repair has a relatively high incidence of recurrence (10%–40%) when the crura is closed primarily with permanent suture. Techniques to reduce hernia recurrence continue to evolve. Most surgeons believe that recurrence may be reduced with the use of synthetic or biologic mesh to reinforce the standard crural closure. Randomized controlled studies have demonstrated a reduction in PEH recurrence rate when mesh was used. Nonabsorbable synthetic mesh must be used carefully and not in a keyhole fashion at the hiatus because of a potential risk of esophagus or gastric erosion and mesh infection. Biologic mesh (acellular porcine dermis, acellular human dermis, porcine small intestinal submucosa) has become more widely used, but these meshes are significantly more expensive than synthetic mesh and the only randomized study supporting biologic mesh usage failed to demonstrate superiority over suture alone, after 5 years of rigorous follow up.

Role of Fundoplication in Giant Hiatal Hernia Repair. Controversy remains as to whether to perform an antireflux procedure at all, in selected cases only, or in all patients. The case against an antireflux procedure rests on the frequency of significant postoperative complications secondary to the fundoplication, as well as the slightly longer operative time and increased cost that additional surgery entails. Most advocate the routine addition of an antireflux procedure following repair of the hernia defect. There are several reasons for this. Physiologic testing with 24-hour esophageal pH monitoring has shown increased esophageal exposure to acid gastric juice in 60% to 70% of patients with a paraesophageal hiatal hernia, nearly identical to the observed 71% incidence in patients with a sliding hiatal hernia. Furthermore, there is no relation between the symptoms experienced by the patient with a PEH and the competency of the cardia. Finally, dissection of the gastroesophageal esophagus may lead to postoperative reflux despite a negative preoperative pH score.

The Short Esophagus and PEH
Giant PEH can be associated with a short esophagus in up to 5% to 20% of patients as a result of chronic cephalad displacement of the GEJ. The presence of a short esophagus increases the difficulty of laparoscopic PEH repair. Approximately 10% to 20% of surgical failures with PEH repair is due to the lack of recognition of a short esophagus. Preoperative results of barium swallow and esophagogastroduodenoscopy may provide an indication of short esophagus, but no combination of preoperative clinical variables reliably predict the presence of short esophagus, defined as the failure to achieve 2.5 cm of intra-abdominal esophagus with standard mediastinal dissection techniques. Hence, the diagnosis of this entity continues to be made definitively only in the operating room. Collis gastroplasty achieves esophageal lengthening by creation of a neoesophagus using the gastric cardia. The totally laparoscopic approach to the short esophagus has evolved from a method using an end-to-end anastomosis circular stapler to the current approach that uses a linear stapler creating a stapled wedge gastroplasty. Elements of importance in fashioning the fundoplication after Collis gastroplasty include placement of the initial suture of the fundoplication on the esophagus, immediately above the GEJ to ensure that acid-secreting (gastric) mucosa does not reside above the fundoplication. A second element that ensures safety and avoids wrap deformation is to place the gastric portion of the staple line against the neoesophagus, such that the tip of the gastric staple line sits adjacent to the middle suture of the fundoplication on the right side of the esophagus.
Results

Most outcome studies report relief of symptoms following surgical repair of PEHs in more than 90% of patients. The current literature suggests that laparoscopic repair of a paraesophageal hiatal hernia can be successful. Most authors report symptomatic improvement in 80% to 90% of patients, and <10% to 15% prevalence of recurrent symptomatic hernia. However, the problem of recurrent asymptomatic or minimally symptomatic hernia following PEH repair, open or laparoscopic, is becoming increasingly appreciated. Recurrent hiatal hernia is the most common cause of anatomic failure following laparoscopic Nissen fundoplication done for GERD (5%–10%), but this risk is compounded for the giant hernia where radiologic recurrence is detected in 25% to 40% of patients. It appears that optimal results with open or laparoscopic giant hiatal hernia repair should include options for mesh buttressing of hiatal closure and selective esophageal lengthening with one of the many techniques developed for the creation of a Collis gastroplasty. Despite this high incidence of radiologic recurrence, and the surgical pursuit of a remedy, it must be reinforced that asymptomatic recurrent hernia, like primary PEH, do not need to be repaired. The risk of incarceration, strangulation, or obstruction is minimal.

SCHATZKI’S RING

Schatzki’s ring is a thin submucosal circumferential ring in the lower esophagus at the squamocolumnar junction, often associated with a hiatal hernia. Its significance and pathogenesis are unclear (Fig. 25-41). The ring was first noted by Templeton, but Schatzki and Gary defined it as a distinct entity in 1953. Its prevalence varies from 0.2% to 14% in the general population, depending on the technique of diagnosis and the criteria used. Stiennon believed the ring to be a pleat of mucosa formed by infolding of redundant esophageal mucosa due to shortening of the esophagus. Others believe the ring to be congenital, and still others suggest it is an early stricture resulting from inflammation of the esophageal mucosa caused by chronic reflux.

Schatzki’s ring is a distinct clinical entity having different symptoms, upper GI function studies, and response to treatment compared with patients with a hiatal hernia, but without a ring. Twenty-four-hour esophageal pH monitoring has shown that patients with a Schatzki’s ring have a lower incidence of reflux than hiatal hernia controls. They also have better LES function. This, together with the presence of a ring, could represent a protective mechanism to prevent gastroesophageal reflux.

Symptoms associated with Schatzki’s ring are brief episodes of dysphagia during hurried ingestion of solid foods. Its treatment has varied from dilation alone to dilation with antireflux measures, antireflux procedure alone, incision, and even excision of the ring. Little is known about the natural progression of Schatzki’s rings. Using radiologic techniques, Chen and colleagues showed progressive stenosis of rings in 59% of patients, whereas Schatzki found that the rings decreased in diameter in 29% of patients and remained unchanged in the rest.

Symptoms in patients with a ring are caused more by the presence of the ring than by gastroesophageal reflux. Most patients with a ring but without proven reflux respond to one dilation, while most patients with proven reflux require repeated dilations. In this regard, the majority of Schatzki’s ring patients without proven reflux have a history of ingestion of drugs known to be damaging to the esophageal mucosa. Bonavina and associates have suggested drug-induced injury as the cause of stenosis in patients with a ring, but without a history of reflux. Because rings also occur in patients with proven reflux, it is likely that gastroesophageal reflux also plays a part. This is supported by the fact that there is less drug ingestion in the history of these patients. Schatzki’s ring is probably an acquired lesion that can lead to stenosis from chemical-induced injury by pill lodgment in the distal esophagus, or from reflux-induced injury to the lower esophageal mucosa.

The best form of treatment of a symptomatic Schatzki’s ring in patients who do not have reflux consists of esophageal dilation for relief of the obstructive symptoms. In patients with a ring who have proven reflux and a mechanically defective sphincter, an antireflux procedure is necessary to obtain relief and avoid repeated dilation.

SCLERODERMA

Scleroderma is a systemic disease accompanied by esophageal abnormalities in approximately 80% of patients. In most, the disease follows a prolonged course. Renal involvement occurs in a small percentage of patients and signals a poor prognosis. The onset of the disease is usually in the third or fourth decade of life, occurring twice as frequently in women as in men.

Small vessel inflammation appears to be an initiating event, with subsequent perivascular deposition of normal collagen, which may lead to vascular compromise. In the GI tract, the predominant feature is smooth muscle atrophy. Whether the atrophy in the esophageal musculature is a primary effect or occurs secondary to a neurogenic disorder is unknown. The results of pharmacologic and hormonal manipulation, with agents that act either indirectly via neural mechanisms or directly on the muscle, suggest that scleroderma is a primary neurogenic disorder. Methacholine, which acts directly on smooth muscle receptors, causes a similar increase in LES pressure in normal

Figure 25-41. Barium esophagogram showing Schatzki’s ring (i.e., a thin circumferential ring in the distal esophagus at the squamocolumnar junction). Below the ring is a hiatal hernia.
controls and in patients with scleroderma. Edrophonium, a cholinesterase inhibitor that enhances the effect of acetylcholine when given to patients with scleroderma, causes an increase in LES pressure that is less marked in these patients than in normal controls, suggesting a neurogenic rather than myogenic etiology. Muscle ischemia due to perivascular compression has been suggested as a possible mechanism for the motility abnormality in scleroderma. Others have observed that in the early stage of the disease, the manometric abnormalities may be reversed by reserpine, an agent that depletes catecholamines from the adrenergic system. This suggests that, in early scleroderma, an adrenergic overactivity may be present that causes a parasympathetic inhibition, supporting a neurogenic mechanism for the disease. In advanced disease manifested by smooth muscle atrophy and collagen deposition, reserpine no longer produces this reversal. Consequently, from a clinical perspective, the patient can be described as having a poor esophageal pump and a poor valve.

The diagnosis of scleroderma can be made manometrically by the observation of normal peristalsis in the proximal striated esophagus, with absent peristalsis in the distal smooth muscle portion (Fig. 25-42). The LES pressure is progressively weakened as the disease advances. Because many of the systemic sequelae of the disease may be nondiagnostic, the motility pattern is frequently used as a specific diagnostic indicator. Gastroesophageal reflux commonly occurs in patients with scleroderma, because they have both hypotensive sphincters and poor esophageal clearance. This combined defect can lead to severe esophagitis and stricture formation. The typical barium swallow shows a dilated, barium-filled esophagus, stomach, and duodenum, or a hiatal hernia with distal esophageal stricture and proximal dilatation (Fig. 25-43).

Traditionally, esophageal symptoms have been treated with PPIs, antacids, elevation of the head of the bed, and multiple dilations for strictures, with generally unsatisfactory results. The degree of esophagitis is usually severe and may lead to marked esophageal shortening as well as stricture. Scleroderma patients have frequently had numerous dilations before they are referred to the surgeon. The surgical management is somewhat controversial, but the majority of opinion suggests that a partial fundoplication (anterior or posterior) performed laparoscopically is the procedure of choice. The need for a partial fundoplication is dictated by the likelihood of severe dysphagia if a total fundoplication is performed in the presence of aperistalsis. Esophageal shortening may require a Collis gastroplasty in combination with a partial fundoplication. Surgery reduces esophageal acid exposure, but does not return it to normal because of the poor clearance function of the body of the esophagus. Only 50% of the patients have a good-to-excellent result. If the esophagitis is severe, or there has been a previous failed antireflux procedure and the disease is associated with delayed gastric emptying, a gastric resection with Roux-en-Y gastrojejunostomy has proved the best option.

Eosinophilic Esophagitis

Eosinophilic esophagitis (EE) was first described in 1977, but has become well known only in the last two decades. The condition
is characterized by a constellation of symptoms, endoscopic and radiologic findings, and distinctive pathology. The etiology of eosinophilic esophagitis is not entirely known but its similarities, immunologically, to asthma suggest that it is a form of “allergic esophagitis.”

**Symptoms**
The presentation of eosinophilic esophagitis is chest pain, (often postprandial) and dysphagia. Dysphagia may occur with liquids or solids, but solid food dysphagia is most common. Because dysphagia and chest pain are characteristic of GERD, EE is often confused with GERD; however, EE does not respond to proton pump inhibitors. The evaluation of the patient with EE and dysphagia and chest pain with esophagram and endoscopy usually reveals the diagnosis.

**Signs**
A barium swallow should be the first test obtained in the patient with dysphagia. EE has a characteristic finding often called the “ringed esophagus” or the “feline esophagus,” as the esophageal rings are felt to look like the stripes on a housecat (Fig. 25-44). The endoscopic appearance of EE is also characteristic, and also appears as a series of rings (Fig. 25-45).

**Pathology**
Endoscopic biopsy specimens should be taken when eosinophilic esophagitis is suspected. To make the diagnosis of EE, the pathologist should see a minimum of 15 eosinophils per high powered field, usually at the base of the epithelium (Fig. 25-46).

**Treatment**
The treatment of EE is largely symptomatic and includes testing for food allergies, and elimination of identified items from the diet. Second line therapy includes inhaled or ingested corticosteroids, as would be used to treat asthma. If dysphagia is not relieved with steroids, it may be necessary to dilate the esophagus. Because of the length of esophageal involvement, rigid dilators (Maloney or Savary) are often used. Great care must be exercised, as the inflamed EE is quite friable. The mucosal tears easily, and esophageal perforation (full thickness laceration) has been reported with EE dilation.

**Figure 25-44.** The esophagus on the left shows a stacking of rings, demonstrating eosinophilic esophagus. The esophagus on the right is a normal barium swallow.

**Figure 25-45.** The endoscopic appearance of eosinophilic esophagitis is characteristically a series of stacked mucosal rings.

---

**MOTILITY DISORDERS OF THE PHARYNX AND ESOPHAGUS**

**Clinical Manifestations**
Dysphagia (i.e., difficulty in swallowing) is the primary symptom of esophageal motor disorders. Its perception by the patient is a balance between the severity of the underlying abnormality causing the dysphagia, and the adjustment made by the patient in altering eating habits. Consequently, any complaint of dysphagia must include an assessment of the patient’s dietary history. It must be known whether the patient experiences pain, chokes, or vomits with eating; whether the patient requires liquids with the meal, is the last to finish, or is forced to interrupt or avoid a social meal; and whether he or she has been admitted to the hospital for food impaction. These assessments, plus an evaluation of the patient’s nutritional status, help to determine how severe the dysphagia is and judge the need for surgical
intervention, rather than more conservative methods of treating dysphagia.

**Motility Disorders of the Pharynx and Upper Esophagus – Transit Dysphagia**

Disorders of the pharyngeal phase of swallowing result from a discoordination of the neuromuscular events involved in chewing, initiation of swallowing, and propulsion of the material from the oropharynx into the cervical esophagus. They can be categorized into one or a combination of the following abnormalities: (a) inadequate oropharyngeal bolus transport; (b) inability to pressurize the pharynx; (c) inability to elevate the larynx; (d) discoordination of pharyngeal contraction and cricopharyngeal relaxation; and (e) decreased compliance of the pharyngoesophageal segment secondary to neuromuscular disease. The latter may result in incomplete relaxation of the cricopharyngeus and cervical esophagus during swallowing. Taken together, these disorders are termed transit dysphagia by many.

Transit dysphagia is usually congenital or results from acquired disease involving the central and peripheral nervous system. This includes cerebrovascular accidents, brain stem tumors, poliomyelitis, multiple sclerosis, Parkinson’s disease, pseudobulbar palsy, peripheral neuropathy, and operative damage to the cranial nerves involved in swallowing. Pure muscular diseases such as radiation-induced myopathy, dermatomyositis, myotonic dystrophy, and myasthenia gravis are less common causes. Rarely, extrinsic compression of the cervical esophagus by thyromegaly, lymphadenopathy, or hyperostosis of the cervical spine can cause transit dysphagia.

**Diagnostic Assessment of the Cricopharyngeal Segment.**

Transit dysphagia difficult to assess with standard manometric techniques because of the rapidity of the oropharyngeal phase of swallowing, the elevation of the larynx, and the asymmetry of the cricopharyngeus. Video- or cineradiography is currently the most objective test to evaluate oropharyngeal bolus transport, pharyngeal compression, relaxation of the pharyngoesophageal segment, and the dynamics of airway protection during swallowing. It readily identifies a diverticulum (Fig. 25-47), stasis of the contrast medium in the valleculae, a cricopharyngeal bar, and/or narrowing of the pharyngoesophageal segment. These are anatomic manifestations of neuromuscular disease, and result from the loss of muscle compliance in portions of the pharynx and esophagus composed of skeletal muscle.

Careful analysis of video- or cineradiographic studies combined with manometry using specially designed catheters can identify the cause of a pharyngoesophageal dysfunction in

most situations (Fig. 25-48). Motility studies may demonstrate inadequate pharyngeal pressurization, insufficient or lack of cricopharyngeal relaxation, marked discoordination of pharyngeal pressurization, cricopharyngeal relaxation and cervical esophageal contraction, or a hypopharyngeal bolus pressure suggesting decreased compliance of the skeletal portion of the cervical esophagus.

In many patients with cricopharyngeal dysfunction, including those with Zenker’s diverticulum, it has been difficult to consistently demonstrate a motility abnormality or discoordination of pharyngoesophageal events. The abnormality most apt to be present is a loss of compliance in the pharyngoesophageal segment manifested by an increased bolus pressure. Cook and colleagues have demonstrated an increased resistance to the movement of a bolus through what appears on manometry to be a completely relaxed cricopharyngeal sphincter. Using simultaneous manometry and videofluoroscopy, they showed that, in these patients, the cricopharyngeus is only partially relaxed; that is, the sphincter is relaxed enough to allow a drop of its pressure to esophageal baseline on manometry, but insufficiently relaxed to allow unimpaired passage of the bolus into the esophagus. This incomplete relaxation is due to a loss of compliance of the muscle in the pharyngoesophageal segment, and may be associated with a cricopharyngeal bar or Zenker’s diverticulum. This decreased compliance of the cricopharyngeal sphincter can be recognized on esophageal manometry by a “shoulder” on the pharyngeal pressure wave, the amplitude of which correlates directly with the degree of outflow obstruction (Fig. 25-49). Increasing the diameter of this noncompliant segment reduces the resistance imposed on the passage of a bolus. Consequently, patients with low pharyngeal pressure (i.e., poor piston function of the pharynx), or patients with increased resistance of the pharyngocervical esophageal segment from loss of skeletal muscle compliance, are improved by a cricopharyngeal myotomy. This enlarges the pharyngoesophageal segment and reduces outflow resistance. Esophageal muscle biopsy specimens from patients with Zenker’s diverticulum have shown histologic evidence of the restrictive myopathy in the cricopharyngeus muscle. These findings correlate well with the observation of a decreased compliance of the upper esophagus demonstrated by videoradiography and the findings on detailed manometric studies of the pharynx and cervical esophagus. They suggest that the diverticulum develops as a consequence of the outflow resistance to bolus transport through the noncompliant muscle of the pharyngoesophageal segment.

The requirements for a successful pharyngoesophageal myotomy are: (a) adequate oropharyngeal bolus transport; (b) the presence of an intact swallowing reflex; (c) reasonable coordination of pharyngeal pressurization with cricopharyngeal relaxation; and (d) a cricopharyngeal bar, Zenker’s diverticulum, or a narrowed pharyngoesophageal segment on videoeosophagogram and/or the presence of excessive pharyngoesophageal shoulder pressure on motility study.

**Zenker’s Diverticulum.** In the past, the most common recognized sign of cricopharyngeal dysfunction was the presence of a Zenker’s diverticulum, originally described by Ludlow in 1769. The eponym resulted from Zenker’s classic clinicopathologic descriptions of 34 cases published in 1878. Pharyngoesophageal diverticula have been reported to occur in 1 of 1000 routine barium examinations, and classically occur in elderly, white males. Zenker’s diverticula tend to enlarge progressively with

time due to the decreased compliance of the skeletal portion of the cervical esophagus that occurs with aging.

Presenting symptoms include dysphagia associated with the spontaneous regurgitation of undigested, bland material, often interrupting eating, or drinking. On occasion, the dysphagia can be severe enough to cause debilitation and significant weight loss. Chronic aspiration and repetitive respiratory infection are common associated complaints. Once suspected, the diagnosis is established by a barium swallow. Endoscopy is usually difficult in the presence of a cricopharyngeal diverticulum, and potentially dangerous, owing to obstruction of the true esophageal lumen by the diverticulum and the attendant risk of diverticular perforation.

**Cricopharyngeal Myotomy.** The low morbidity and mortality associated with cricopharyngeal and upper esophageal myotomy have encouraged a liberal approach toward its use for almost any problem in the oropharyngeal phase of swallowing. This attitude has resulted in an overall success rate in the relief of symptoms of only 64%. When patients are selected for surgery using radiographic or motility markers of disease, a much higher proportion will benefit. Two methods of cricopharyngeal myotomy are in common use, one using traditional surgical approaches, and one using rigid laryngoscopy and a linear cutting stapler.

**Open Cricopharyngeal Myotomy, Diverticulopexy, and Diverticulectomy.** The myotomy can be performed under local or general anesthesia through an incision along the anterior border of the left sternocleidomastoid muscle. The pharynx and cervical esophagus are exposed by retracting the sternocleidomastoid muscle and carotid sheath laterally, and the thyroid, trachea, and larynx medially (Fig. 25-50). When a pharyngoesophageal diverticulum is present, localization of the pharyngoesophageal segment. Under general anesthesia, and in the absence of a diverticulum, the placement of a nasogastric tube to the level of the manometrically determined cricopharyngeal sphincter helps in localization of the structures. The myotomy is extended cephalad by dividing 1 to 2 cm of inferior constrictor muscle of the pharynx, and caudad by dividing the cricopharyngeal muscle and the cervical esophagus for a length of 4 to 5 cm. The cervical wound is closed only when all oozing of blood has ceased, because a hematoma after this procedure is common, and is often associated with temporary dysphagia while the hematoma absorbs. Oral alimentation is started the day after surgery. The patient is usually discharged on the first or second postoperative day.

If a diverticulum is present and is large enough to persist after a myotomy, it may be sutured in the inverted position to the prevertebral fascia using a permanent suture (i.e., diverticulopexy) (Fig. 25-51). If the diverticulum is excessively large so that it would be redundant if suspended, or if its walls are thickened, a diverticulectomy should be performed. This is best performed under general anesthesia by placing a Maloney dilator (48F) in the esophagus, after controlling the neck of the diverticulum and after myotomy. A linear stapler is placed across the neck of the diverticulum and the diverticulum is excised distal to the staple line. The security of this staple line and effectiveness of the myotomy may be tested before hospital discharge with a water soluble contrast esophagogram. Postoperative complications include fistula formation, abscess, hematoma, recurrent nerve paralysis, difficulties in phonation, and Horner’s syndrome. The incidence of the first two can be reduced by performing a diverticulopexy rather than diverticulectomy.

**Endoscopic Cricopharyngotomy.** Endoscopic stapled cricopharyngotomy and diverticulectomy recently has been described. This procedure is most effective for larger diverticula (>2 cm), and may be impossible to perform for the small diverticulum. The procedure uses a specialized “diverticuloscope” with two retractable valves passed into the hypopharynx. The lips of the diverticuloscope are positioned so that one lip lies in the esophageal lumen and the other in the diverticular lumen. The valves of the diverticuloscope are retracted appropriately so as to visualize the septum interposed between the diverticulum and the esophagus. An endoscopic linear stapler is introduced into the diverticuloscope and positioned against the common septum with...
the anvil in the diverticulum and the cartridge in the esophageal lumen. Firing of the stapler divides the common septum between the posterior esophageal and the diverticular wall over a length of 30 mm, placing three rows of staples on each side. More than one stapler application may be needed, depending on the size of the diverticulum (Fig. 25-52). The patient is allowed to resume liquid feeds immediately, and is usually discharged the day after surgery. Complications are rare and may include perforation at the apex of the diverticulum, and failure to relieve dysphagia resulting from incomplete myotomy. The former complication can usually be treated with antibiotics, but may rarely require neck drainage.

Recurrence of a Zenker’s diverticulum may occur with long follow-up, and is more common after diverticulectomy without myotomy, presumably due to persistence of the underlying loss of compliance of the cervical esophagus when a myotomy is not performed. After endoscopic cricopharyngotomy lateral residual “pouches” may be seen on radiographs, but are rarely responsible for residual or recurrent symptoms if the myotomy has been complete. Postoperative motility studies have shown that the peak pharyngeal pressure generated on swallowing is not affected, the resting cricopharyngeal pressure is reduced but not eliminated, and the cricopharyngeal sphincter length is shortened. Consequently, after myotomy, there is protection against esophagopharyngeal regurgitation.

**Motility Disorders of the Esophageal Body and Lower Esophageal Sphincter**

Disorders of the esophageal phase of swallowing result from abnormalities in the propulsive pump action of the esophageal body or the relaxation of the LES. These disorders result from either primary esophageal abnormalities, or from generalized neural, muscular, or collagen vascular disease (Table 25-8). The use of standard and high-resolution esophageal manometry techniques has allowed specific primary esophageal motility disorders to be identified out of a pool of nonspecific motility abnormalities. Primary esophageal motor disorders include achalasia, DES, nutcracker esophagus, and the hypertensive LES. The manometric characteristics of these disorders are shown in Table 25-9.

The boundaries between the primary esophageal motor disorders are vague, and intermediate types exist, some of which may combine more than one type of motility pattern. These findings indicate that esophageal motility disorders should be looked at as a spectrum of abnormalities that reflects various stages of destruction of esophageal motor function.

**Achalasia.** The best known and best understood primary motility disorder of the esophagus is achalasia, with an incidence of six per 100,000 population per year. Although complete absence of peristalsis in the esophageal body has been proposed as the major abnormality, present evidence indicates achalasia is a primary disorder of the LES. This is based on 24-hour outpatient esophageal motility monitoring, which shows that, even in advanced disease, up to 5% of contractions can be peristaltic. Simultaneous esophageal waves develop as a result of the increased resistance to esophageal emptying caused by the

The ganglia in the myenteric plexus of the esophagus itself. Invasive changes have been shown in the vagus nerve and in the nucleus of the vagus nerve. In patients with the disease, degenerative degeneration, which is either idiopathic or due to infection. In experimental animals, the disease has been reproduced by the increased outflow obstruction of the esophageal body can be caused by the increased outflow obstruction of a nonrelaxing sphincter. This conclusion is supported by experimental studies in which a band placed loosely around the GEJ in experimental models did not change sphincter pressures, but resulted in impaired relaxation of the LES and outflow resistance. This led to a markedly increased frequency of simultaneous waveforms and a decrease in contraction amplitude. The changes were associated with radiographic dilation of the esophagus and were reversible after removal of the band. Observations in patients with pseudoachalasia due to tumor infiltration, or an antireflux procedure that is too tight also provide evidence that dysfunction of the esophageal body can be caused by the increased outflow obstruction of a nonrelaxing LES. The observation that esophageal peristalsis can return in patients with classic achalasia following dilation or myotomy provides further support that achalasia is a primary disease of the LES.

The pathogenesis of achalasia is presumed to be a neurogenic degeneration, which is either idiopathic or due to infection. In experimental animals, the disease has been reproduced by destruction of the nucleus ambiguus and the dorsal motor nucleus of the vagus nerve. In patients with the disease, degenerative changes have been shown in the vagus nerve and in the ganglia in the myenteric plexus of the esophagus itself. This degeneration results in hypertension of the LES, a failure of the sphincter to relax on swallowing, elevation of intraluminal esophageal pressure, esophageal dilatation, and a subsequent loss of progressive peristalsis in the body of the esophagus. The esophageal dilatation results from the combination of a nonrelaxing sphincter, which causes a functional retention of ingested material in the esophagus, and elevation of intraluminal pressure from repetitive pharyngeal air swallowing (Fig. 25-53). With time, the functional disorder results in anatomic alterations seen on radiographic studies, such as a dilated esophagus with a tapering, “bird’s beak”-like narrowing of the distal end (Fig. 25-54). There is usually an air-fluid level in the esophagus from the retained food and saliva, the height of which reflects the degree of resistance imposed by the nonrelaxing sphincter. As the disease progresses, the esophagus becomes massively dilated and tortuous.

A subgroup of patients with otherwise typical features of classic achalasia has simultaneous contractions of their esophageal body that can be of high amplitude. This manometric pattern has been termed vigorous achalasia, and chest pain episodes.

Figure 25-53. Pressurization of esophagus: Ambulatory motility tracing of a patient with achalasia. A. Before esophageal myotomy. B. After esophageal myotomy. The tracings have been compressed to exaggerate the motility spikes and baseline elevations. Note the rise in esophageal baseline pressure during a meal represented by the rise off the baseline to the left of panel A. No such rise occurs postmyotomy (panel B).
are a common finding in these patients. Since the development of high-resolution esophageal manometry technology, the term vigorous achalasia has been replaced with Chicago type 3 achalasia. Differentiation of type 3 achalasia from DES can be difficult. In both diseases, videoradiographic examination may show a corkscrew deformity of the esophagus and diverticulum formation.

**Diffuse and Segmental Esophageal Spasm.** DES is characterized by substernal chest pain and/or dysphagia. DES differs from classic achalasia in that it is primarily a disease of the esophageal body, produces a lesser degree of dysphagia, causes more chest pain, and has less effect on the patient’s general condition. Nonetheless, it is impossible to differentiate achalasia from DES on the basis of symptoms alone. Esophagogram and esophageal manometry are required to distinguish these two entities. True symptomatic DES is a rare condition, occurring about five times less frequently than achalasia.

The causation and neuromuscular pathophysiology of DES are unclear. The basic motor abnormality is rapid wave progression down the esophagus secondary to an abnormality in the latency gradient. Hypertrophy of the muscular layer of the esophageal wall and degeneration of the esophageal branches of the vagus nerve have been observed in this disease, although these are not constant findings. Manometric abnormalities in DES may be present over the total length of the esophageal body, but usually are confined to the distal two thirds. In segmental esophageal spasm, the manometric abnormalities are confined to a short segment of the esophagus.

The LES in patients with DES usually shows a normal resting pressure and relaxation on swallowing. A hypertensive sphincter with poor relaxation may also be present. In patients with advanced disease, the radiographic appearance of tertiary contractions appears helical, and has been termed corkscrew esophagus or pseudodiverticulosis (Fig. 25-55). Patients with segmental or diffuse esophageal spasm can compartmentalize the esophagus and develop an epiphrenic or midesophageal diverticulum between two areas of high pressure occurring simultaneously (Fig. 25-56).

**Nutcracker Esophagus.** The disorder, termed nutcracker or supersqueezer esophagus, was recognized in the late 1970s. Other terms used to describe this entity are hypertensive peristalsis or high-amplitude peristaltic contractions. It is the most common of the primary esophageal motility disorders. By definition the so-called nutcracker esophagus is a manometric abnormality in patients who are characterized by peristaltic esophageal contractions with peak amplitudes greater than two SDs above the normal values in individual laboratories. Contraction amplitudes in these patients can easily be above 400 mmHg. At the lower end of peak pressure, it is unclear whether nutcracker esophagus causes any symptoms. In fact,
syndrome, exhibits severe esophageal motility disorders. It is likely that myotomy will provide more permanent benefit. If symptoms are relieved (temporarily) with this technique, then it is possible to inject the LES with botulinum toxin, endoscopically. If symptom contribution to medical therapy or dilation. When the symptom contribution of the hypertensive sphincter is in doubt, it is possible to inject the LES with botulinum toxin, endoscopically. If symptoms are relieved (temporarily) with this technique, then it is likely that myotomy will provide more permanent benefit.

Myotomy of the LES may be indicated in patients who do not respond to medical therapy or dilation. When the symptom contribution of the hypertensive sphincter is in doubt, it is possible to inject the LES with botulinum toxin, endoscopically. If symptoms are relieved (temporarily) with this technique, then it is likely that myotomy will provide more permanent benefit.

Secondary Esophageal Motility Disorders. Connective tissue disease, particularly scleroderma and the CREST syndrome, exhibits severe esophageal motility disorders. Additionally, patients treated as infants for esophageal atresia will often develop secondary motility disorders manifest later in life. Symptoms of these disorders are heartburn and dysphagia. The latter may be a result of a peptic stricture rather than the esophageal dysmotility. An esophageal motility study will usually show severely reduced or absent peristalsis with severely reduced or absent LES pressure. The role of antireflux surgery under these conditions is controversial, but, if performed, should be limited to partial fundoplication, as full (Nissen) fundoplication may result in severe dysphagia.

Nonspecific Esophageal Motor Disorders and Ineffective Esophageal Motility. Many patients complaining of dysphagia or chest pain of noncardiac origin demonstrate a variety of wave patterns and contraction amplitudes on esophageal manometry that are clearly out of the normal range, but do not meet the criteria of a primary esophageal motility disorder. Esophageal motility in these patients frequently shows an increased number of multiphasic or repetitive contractions, contractions of prolonged duration, nontransmitted contractions, an interruption of a peristaltic wave at various levels of the esophagus, or contractions of low amplitude. These motility abnormalities have been termed nonspecific esophageal motility disorders. Their significance in the causation of chest pain or dysphagia is still unclear. Surgery plays no role in the treatment of these disorders unless there is an associated diverticulum.

A clear distinction between primary esophageal motility disorders and nonspecific esophageal motility disorders is often not possible. Patients diagnosed as having nonspecific esophageal motility abnormalities on repeated studies will occasionally show abnormalities consistent with nutcracker esophagus. Similarly, progression from a nonspecific esophageal motility disorder to classic DES has been demonstrated. Therefore, the finding of a nonspecific esophageal motility disorder may represent only a manometric marker of an intermittent, more severe esophageal motor abnormality. Combined ambulatory 24-hour esophageal pH and motility monitoring has shown that an increased esophageal exposure to gastric juice is common in patients diagnosed as having a nonspecific esophageal motility disorder. In some situations, the motor abnormalities may be induced by the irritation of refluxed gastric juice; in other situations, it may be a primary event unrelated to the presence of reflux. High-amplitude peristalsis (nutcracker esophagus) and low-amplitude peristalsis (ineffective esophageal motility) are frequently associated with GERD.

Diverticula of the Esophageal Body. Diverticula of the esophagus may be characterized by their location in the esophagus (proximal, mid-, or distal esophagus), or by the nature of concomitant pathology. Diverticula associated with motor disorders are termed pulsion diverticula and those associated with inflammatory conditions are termed traction diverticula. Pulsion diverticula occur most commonly with nonspecific motility disorders, but can occur with all of the primary motility disorders. In the latter situation, the motility disorder is usually diagnosed before the development of the diverticulum. When associated with achalasia, the development of a diverticulum may temporarily alleviate the symptom of dysphagia by becoming a receptacle for ingested food, and substitute the symptom of dysphagia for postprandial pain and regurgitation of undigested food. If a motility abnormality of the esophageal body or LES cannot be identified, a traction or congenital cause for the diverticulum should be considered.
Because development in radiology preceded development in motility monitoring, diverticula of the esophagus were considered historically to be a primary abnormality, the cause, rather than the consequence, of motility disorders. Consequently, earlier texts focused on them as specific entities based upon their location.

Epiphrenic diverticula arise from the terminal third of the thoracic esophagus and are usually found adjacent to the diaphragm. They have been associated with distal esophageal muscular hypertrophy, esophageal motility abnormalities, and increased luminal pressure. They are “pulsion” diverticula, and are associated with diffuse spasm, achalasia, or nonspecific motor abnormalities in the body of the esophagus.

Whether the diverticulum should be surgically resected or suspended depends on its size and proximity to the vertebral body. When diverticula are associated with esophageal motility disorders, esophageal myotomy from the proximal extent of the diverticulum to the stomach should be combined with diverticulectomy. If diverticulectomy alone is performed, one can expect a high incidence of suture line rupture due to the same intraluminal pressure that initially gave rise to the diverticulum. If the diverticulum is suspended to the prevertebral fascia of the thoracic vertebra, a myotomy is begun at the neck of the diverticulum and extended across the LES. If the diverticulum is excised by dividing the neck, the muscle is closed over the excision site and a myotomy is performed on the opposite esophageal wall, starting just above the level of the diverticulum or at the proximal extent of the spastic segment of the esophagus if high resolution motility is used. If complete, the myotomy will cross the LES, reducing distal esophageal peak pressure, and will increase the likelihood that dysphagia will be replaced with GERD symptoms. Increasingly, partial fundoplication (anterior or posterior) is performed after LES myotomy to decrease the frequency of disabling GERD developing after myotomy and diverticulectomy. When a large diverticulum is associated with a hiatal hernia, then hiatal hernia repair is added. All these procedures may be performed with traditional or minimally invasive techniques.

Midesophageal or traction diverticula were first described in the nineteenth century (Fig. 25-57). At that time, they were frequently noted in patients who had mediastinal LN involvement with tuberculosis. It was theorized that adhesions formed between the inflamed mediastinal nodes and the esophagus. By contraction, the adhesions exerted traction on the esophageal wall and led to a localized diverticulum (Fig. 25-58). This theory was based on the findings of early dissections, where adhesions between diverticula and LNs were commonly found. Other conditions associated with mediastinal lymphadenopathy, such as pulmonary fungal infections (e.g., aspergillosis), lymphoma, or sarcoid, may create traction esophageal diverticula after successful treatment. Rarely, when no underlying inflammatory pathology is identified, a motility disorder may be identified.

Most midesophageal diverticula are asymptomatic and incidentally discovered during investigation for nonesophageal complaints. In such patients, the radiologic abnormality may be ignored. Patients with symptoms of dysphagia, regurgitation, chest pain, or aspiration, in whom a diverticulum is discovered, should be thoroughly investigated for an esophageal motor abnormality. Occasionally, a patient will present with a bronchoesophageal fistula manifested by a chronic cough on ingestion of meals. The diverticulum in such patients is most likely to have an inflammatory etiology.

The indication for surgical intervention is dictated by the degree of symptomatic disability. Usually, midesophageal diverticula can be suspended due to their proximity to the spine. If a motor abnormality is documented, a myotomy should be performed as described for an epiphrenic diverticulum.
Long Esophageal Myotomy for Motor Disorders of the Esophageal Body

A long esophageal myotomy is indicated for dysphagia caused by any motor disorder characterized by segmental or generalized simultaneous waveforms in a patient whose symptoms are not relieved by medical therapy. Such disorders include diffuse and segmental esophageal spasm, vigorous or Type 3 achalasia, and nonspecific motility disorders associated with a mid- or epiphrenic esophageal diverticulum. However, the decision to operate must be made by a balanced evaluation of the patient’s symptoms, diet, lifestyle adjustments, and nutritional status, with the most important factor being the possibility of improving the patient’s swallowing disability. The symptom of chest pain alone is not an indication for a surgical procedure.

The identification of patients with symptoms of dysphagia and chest pain who might benefit from a surgical myotomy is difficult. Ambulatory motility studies have shown that when the prevalence of “effective contractions” (i.e., peristaltic waveforms consisting of contractions with an amplitude above 30 mmHg) drops below 50% during meals, the patient is likely to experience dysphagia (Fig. 25-59). This would suggest that relief from the symptom can be expected with an improvement of esophageal contraction amplitude or amelioration of nonperistaltic waveforms. Prokinetic agents may increase esophageal contraction amplitude, but do not alter the prevalence of simultaneous waveforms. Patients in whom the efficacy of esophageal propulsion is severely compromised because of a high prevalence of simultaneous waveforms usually receive little benefit from medical therapy. In these patients, a surgical myotomy of the esophageal body can improve the patients’ dysphagia, provided the loss of contraction amplitude in the remaining peristaltic waveforms, caused by the myotomy, has less effect on swallowing function than the presence of the excessive simultaneous contractions. This situation is reached when the prevalence of effective waveforms during meals drops below 30%, (i.e., 70% of esophageal waveforms are ineffective).

In patients selected for surgery, preoperative high resolution manometry is essential to determine the proximal extent of the esophageal myotomy. Most surgeons extend the myotomy distally across the LES to reduce outflow resistance. Consequently, some form of antireflux protection is needed to avoid gastroesophageal reflux if there has been extensive dissection of the cardia. In this situation, most authors prefer a partial, rather than a full, fundoplication, in order not to add back-resistance that will further interfere with the ability of the myotomized esophagus to empty (Fig. 25-60). If the symptoms of reflux are present preoperatively, 24-hour pH monitoring is required to confirm its presence.

The procedure may be performed either open or via thoracoscopy. The open technique is performed through a left thoracotomy in the sixth intercostal space (Fig. 25-61). An incision is made in the posterior mediastinal pleura over the esophagus, and the left lateral wall of the esophagus is exposed. The esophagus is not circumferentially dissected unless necessary. A 2-cm incision is made into the abdomen through the parietal peritoneum at the midportion of the left crus. A tongue of gastric fundus is pulled into the chest. This exposes the GEJ and its associated fat pad. The latter is excised to give a clear view of the junction. A myotomy is performed through all muscle layers, extending distally over the stomach 1 to 2 cm below the GEJ, and proximally on the esophagus over the distance of the manometric abnormality. The muscle layer is dissected from the mucosa laterally for a distance of 1 cm. Care is taken to divide all minute muscle bands, particularly in the area of the GEJ. The gastric fundic tongue is sutured to the margins of the myotomy over a distance of 3 to 4 cm and replaced into the abdomen. This maintains separation of the muscle and acts as a partial fundoplication to prevent reflux.

If an epiphrenic diverticulum is present, it is excised by dividing the neck with a stapler sized for the thickness of the diverticulum (2.0- to 4.8-mm staple leg length) followed by a closure of the muscle over the staple line, when possible. The myotomy is then performed on the opposite esophageal wall. If a midesophageal diverticulum is present, the myotomy is made so that it includes the muscle around the neck, and the diverticulum is suspended by attaching it to the paravertebral fascia of the thoracic vertebra above the level of the diverticular neck. Before performing any operation for an esophageal diverticulum,

it is wise to endoscope the patient to wash all food and other debris from the diverticulum. The results of myotomy for motor disorders of the esophageal body have improved in parallel with the improved preoperative diagnosis afforded by manometry. Previous published series report between 40% and 92% improvement of symptoms, but interpretation is difficult due to the small number of patients involved and the varying criteria for diagnosis of the primary motor abnormality. When myotomy is accurately done, 93% of the patients have effective palliation of dysphagia after a mean follow-up of 5 years, and 89% would have the procedure again, if it was necessary. Most patients gain or maintain rather than lose weight after the operation. Postoperative motility studies show that the myotomy reduces the amplitude of esophageal contractions to near zero and eliminates simultaneous peristaltic waves. If the benefit of obliterating the simultaneous waves exceeds the adverse effect on bolus propulsion caused by the loss of peristaltic waves, the patient’s dysphagia is likely to be improved by the procedure. If not, the patient is likely to continue to complain of dysphagia and to have little improvement as a result of the operation.

The thoracoscopic technique may be performed through the left or right chest. There has been little experience gained with doing adequate operations (as described previously with the open exposure) through left thoracoscopy, so most surgeons will combine a right thoracoscopic long myotomy with an abdominal approach for Heller myotomy and partial fundoplication. These two procedures may be done at the same setting, by double positioning the patient, or they may be done at two operations. If this is the case, it is best to do the abdominal component first, as the esophageal outflow obstruction is the source of most of the symptoms. Performing abdominal myotomy (and diverticulectomy, if present) may be all that is required.

A new procedure, peroral endoscopic myotomy (POEM) allows a long myotomy to be performed from the lumen of the esophagus with an endoscope. This procedure is attractive for—among others with Type 3 achalasia (vigorous achalasia) where it is necessary to divide esophagogastric circular muscle on both sides of the diaphragm to the extent that might not be possible with laparoscopy or thoracoscopy alone. The POEM procedure is started by opening the esophageal mucosa several centimeters above the spastic segment with a needle–knife electrosurgery device passed through an endoscope. A long submucosal plane is developed with the endoscope, down to and below the LES. The circular muscle of the LES and the esophagus is divided with endoscopic electrosurgery all the way back until normal (nonspastic) esophagus is reached. The submucosal entry site in the esophagus is then closed with endoscopic clips. While the results of POEM are still accumulating, the procedure is attractive because it is extremely minimally invasive, and can be done as an outpatient.

Epiphrenic diverticula cannot be treated with POEM and are most frequently addressed with laparoscopic access, in combination with a laparoscopic division of the LES (Heller myotomy) (Fig. 25-62). If the diverticulum can be completely mobilized through the hiatus, it may be safely excised from below. The neck of the diverticulum is transected with a GIA stapler after passage of a 48F dilator. Not infrequently, the diverticulum is sufficiently large that access to the neck of the diverticulum across the hiatus is quite difficult. Additionally, the inflammatory reaction to the diverticulum may further make the transhiatal dissection difficult. Under these circumstances, it is safer to perform the diverticulectomy through a right thoracoscopic approach either at the time of the initial procedure or at a later date, depending upon the frailty of the patient. Following diverticulectomy, it is critical that the esophageal staple line be treated with a great deal of care. Closure of the muscle over the staple line is preferable. Additionally, the patient is kept NPO or on clear liquids for 5 to 7 days and a contrast study is obtained before advancing to a full liquid or “mushy food” diet. Solid foods are withheld for 2 weeks to decrease the likelihood of staple line leak. Buttressing or sealing the staple line with fibrin glue is also an attractive option.

**Myotomy of the Lower Esophageal Sphincter (Heller Myotomy)**

Second only to reflux disease, achalasia is the most common functional disorder of the esophagus to require surgical intervention. The goal of treatment is to relieve the functional outflow obstruction secondary to the loss of relaxation and
compliance of the LES. This requires disrupting the LES muscle. When performed adequately (i.e., reducing sphincter pressure to <10 mmHg), and done early in the course of disease, LES myotomy results in symptomatic improvement with the occasional return of esophageal peristalsis. Reduction in LES resistance can be accomplished intraluminally by hydrostatic balloon dilation, which ruptures the sphincter muscle, by botulinum toxin injection, or by a surgical myotomy that cuts the sphincter. The difference between these three methods appears to be the greater likelihood of reducing sphincter pressure to <10 mmHg by surgical myotomy compared with hydrostatic balloon dilation. However, patients whose sphincter pressure has been reduced by hydrostatic balloon dilation to <10 mmHg have an outcome similar to those after surgical myotomy (Fig. 25-63). Botulinum toxin injection may achieve similar results, but has a longer duration of action that may be measured in weeks or months, rather than years. Botulinum toxin injection may best be used as a diagnostic tool, when it is not clear whether a hypertensive LES is the primary cause of dysphagia. Responsiveness to botulinum toxin injection may predict a good response to Heller myotomy.

The therapeutic decisions regarding the treatment of patients with achalasia center on four issues. The first issue is the question of whether newly diagnosed patients should be treated with pneumatic dilation or a surgical myotomy. Long-term follow-up studies have shown that pneumatic dilation achieves adequate relief of dysphagia and pharyngeal regurgitation in 50% to 60% of patients (Fig. 25-64). Close follow-up is required, and if dilation fails, myotomy is indicated. For those patients who have a dilated and tortuous esophagus or
an associated hiatal hernia, balloon dilation is dangerous and surgery is the better option. The outcome of the one controlled randomized study (38 patients) comparing the two modes of therapy suggests that surgical myotomy as a primary treatment gives better long-term results. Several randomized trials comparing laparoscopic cardiomyotomy with balloon dilation or botulinum toxin injection have favored the surgical approach as well. Although it has been reported that a myotomy after previous balloon dilation is more difficult, this has not been the experience of these authors unless the cardia has been ruptured in a sawtooth manner. In this situation, operative intervention, either immediately or after healing has occurred, can be difficult. Similarly, myotomy after botulinum toxin injection has reported to be more difficult, but this is largely a function of the submucosal inflammatory response, which may be a bit unpredictable, and is most intense in the first 6 to 12 weeks after injection. It is important to wait at least 3 months after botulinum toxin injection to perform cardiomyotomy to minimize the risk of encountering dense inflammation.

The second issue is the question of whether a surgical myotomy should be performed through the abdomen or the chest. Myotomy of the LES can be accomplished via either an abdominal or thoracic approach. In the absence of a previous upper abdominal surgery, most surgeons prefer the abdominal approach to LES myotomy as laparoscopy results in less pain and a shorter length of stay than thoracoscopy. In addition, it is a bit easier to ensure a long gastric myotomy when the approach is transabdominal.

The third issue—and one that has been long debated—is the question of whether an antireflux procedure should be added to a surgical myotomy. Excellent results have been reported following meticulously performed myotomy without an antireflux component. Retrospective studies, with long-term follow-up of large cohorts of patients undergoing Heller myotomy demonstrated that, after 10 years, more than 50% of patients had reflux symptoms without a fundoplication. In a recent randomized clinical trial, 7% of patients undergoing Dor fundoplication following LES myotomy had abnormal 24-hour pH probes, and 42% of patients with a myotomy only had abnormal reflux profiles. If an antireflux procedure is used as an adjunct to esophageal myotomy, a complete 360° fundoplication should be avoided. Rather, a 270° Belsey fundoplication, a Toupet posterior 180° fundoplication, or a Dor anterior 180° fundoplication should be used to avoid the long-term esophageal dysfunction secondary to the outflow obstruction afforded by the fundoplication itself.

The fourth issue centers on whether or not a cure of this disease is achievable. Long-term follow-up studies after surgical myotomy have shown that late deterioration in results occurs after this procedure, regardless of whether an antireflux procedure is done, and also after balloon dilation, even when the sphincter pressure is reduced to below 10 mm Hg. It may be that, even though a myotomy or balloon rupture of the LES muscle reduces the outflow obstruction at the cardia, the underlying motor disorder in the body of the esophagus persists and deteriorates further with the passage of time, leading to increased impairment of esophageal emptying. The earlier an effective reduction in outflow resistance can be accomplished, the better the outcome will be, and the more likely some esophageal body function can be restored.

In performing a surgical myotomy of the LES, there are four important principles: (a) complete division of all circular and collagen-sling muscle fibers, (b) adequate distal myotomy to reduce outflow resistance, (c) “undermining” of the muscularis to allow wide separation of the esophageal muscle, and (d) prevention of postoperative reflux. In the past, the drawback of a surgical myotomy was the need for an open procedure, which often deterred patients from choosing the best treatment option for achalasia. With the advent of minimally invasive surgical techniques two decades ago, laparoscopic cardiomyotomy (Heller myotomy) has become the treatment of choice for most patients with achalasia.
Open Esophageal Myotomy

Open techniques of distal esophageal myotomy are rarely used outside reoperations. In fact, primary procedures can almost always be successfully completed via laparoscopy. A modified Heller myotomy can be performed through a left thoracotomy incision in the sixth intercostal space along the upper border of the seventh rib. The esophagus and a tongue of gastric fundus are exposed as described for a long myotomy. A myotomy through all muscle layers is performed, extending distally over the stomach to 1 to 2 cm below the junction, and proximally on the esophagus for 4 to 5 cm. The cardia is reconstructed by suturing the tongue of gastric fundus to the margins of the myotomy, to prevent rehaling of the myotomy site, and to provide reflux protection in the area of the divided sphincter. If an extensive dissection of the cardia has been done, a more formal Belsey repair is performed. The tongue of gastric fundus is allowed to retract into the abdomen. Traditionally, nasogastric drainage is maintained for 6 days to prevent distention of the stomach during healing. An oral diet is resumed on the seventh day, after a barium swallow study shows unobstructed passage of the bolus into the stomach without extravasation.

In a randomized, long-term follow-up by Csendes and colleagues of 81 patients treated for achalasia, either by forceful dilation or by surgical myotomy, myotomy was associated with a significant increase in the diameter at the GEJ and a decrease in the diameter at the middle third of the esophagus on follow-up radiographic studies. There was a greater reduction in sphincter pressure and improvement in the amplitude of esophageal contractions after myotomy. After dilation, 13% of patients regained some peristalsis, compared with 28% after surgery. These findings were shown to persist over a 5-year follow-up period, at which time 95% of those treated with surgical myotomy were doing well. Of those who were treated with dilation, only 54% were doing well, while 16% required redilation, and 22% eventually required surgical myotomy to obtain relief.

If simultaneous esophageal contractions are associated with the sphincter abnormality, the so-called vigorous achalasia, then the myotomy should extend over the distance of the abnormal motility as mapped by the preoperative motility study. Failure to do this will result in continuing dysphagia and a dissatisfied patient. The best objective evaluation of improvement in the patient following either balloon dilation or myotomy is a scintigraphic measurement of esophageal emptying time. A good therapeutic response improves esophageal emptying toward normal. However, some degree of dysphagia may persist despite improved esophageal emptying, due to disturbances in esophageal body function. When an antireflux procedure is added to the myotomy, it should be a partial fundoplication. A 360° fundoplication is associated with progressive retention of swallowed food, regurgitation, and aspiration to a degree that exceeds the patient’s preoperative symptoms.

Laparoscopic Cardiomyotomy

More commonly known as a laparoscopic Heller myotomy, after Ernst Heller, a German surgeon who described a “double myotomy” in 1913, the laparoscopic approach is similar to the Nissen fundoplication in terms of the trocar placement and exposure and dissection of the esophageal hiatus (Fig. 25-65). The procedure begins by division of the short gastric vessels in preparation for fundoplication. Exposure of the GEJ via removal of the gastroesophageal fat pad follows. The anterior vagus nerve is swept right laterally along with the fat pad. Once completed, the GEJ and distal 4 to 5 cm of esophagus should be bare of any overlying tissue, and generally follows dissection of the GEJ. A distal esophageal myotomy is performed. It is generally easiest to begin the myotomy 1 to 2 cm above the GEJ, in an area above that of previous botulinum toxin injections or balloon dilation. Either scissors or a hook-type electrocautery can be used to initiate the incision in the longitudinal and circular muscle. Distally, the myotomy is carried across the GEJ and onto the proximal stomach for approximately 2 to 3 cm. After completion, the muscle edges are separated bluntly from the esophageal mucosa for approximately 50% of the esophageal circumference. An antireflux procedure follows completion of the myotomy. Either an anterior hemifundoplication augmenting the angle of His (Dor) or posterior partial fundoplication (Toupet) can be performed. The Dor type fundoplication is slightly easier to perform, and does not require disruption of the normal posterior gastroesophageal attachments (a theoretical advantage in preventing postoperative reflux).

Per Oral Endoscopic Myotomy (POEM)

The POEM procedure was developed in Japan. It is the ultimate minimally invasive myotomy as it requires no incisions through the skin. With the POEM procedure a very effective myotomy is performed entirely from the lumen of the esophagus. The POEM procedure is started by opening the esophageal mucosa 10 cm above the lower esophageal sphincter with a needle-knife electrosurgery device passed through an endoscope. A long submucosal plane is developed with the endoscope, down to and below the LES. The circular muscle of the LES, above and below the gastroesophageal junction is divided with endoscopic electrosurgery. The submucosal entry site in the esophagus is then closed with endoscopic clips. While the results of POEM are still accumulating, the procedure is attractive because it is extremely minimally invasive, and can be done as an outpatient. The major downside of POEM is that an effective antireflux valve cannot be created, exposing the patient to a 40%–50% risk of GERD post procedure.

Outcome Assessment of the Therapy for Achalasia

Critical analysis of the results of therapy for motor disorders of the esophagus requires objective measurement. The use of symptoms alone as an endpoint to evaluate therapy for achalasia may be misleading. The propensity for patients to unconsciously modify their diet to avoid difficulty swallowing is underestimated, making an assessment of results based on symptoms unreliable. Insufficient reduction in outflow resistance may allow progressive esophageal dilation to develop slowly, giving the impression of improvement because the volume of food able to be ingested with comfort increases. A variety of objective measurements may be used to assess success, including LES pressure, esophageal baseline pressure, and scintigraphic assessment of esophageal emptying time. Esophageal baseline pressure is usually negative compared to gastric pressure. Given that the goal of therapy is to eliminate the outflow resistance of a nonrelaxing sphincter, measurement of improvements in esophageal baseline pressure and scintigraphic transit time may be better indicators of success, but are rarely reported.

Eckardt and associates investigated whether the outcome of pneumatic dilation in patients with achalasia could be predicted on the basis of objective measurements. Postdilation LES pressure was the most valuable measurement for predicting
long-term clinical response. A postdilatation sphincter pressure <10 mmHg predicted a good response. Approximately 50% of the patients studied had postdilatation sphincter pressures between 10 and 20 mmHg, with a 2-year remission rate of 71%. More important, 16 of 46 patients were left with a postdilatation sphincter pressure of >20 mmHg, and had an unacceptable outcome. Overall, only 30% of patients dilated remained in symptomatic remission at 5 years.

Bonavina and colleagues reported good to excellent results with transabdominal myotomy and Dor fundoplication in 94% of patients after a mean follow-up of 5.4 years. No operative mortality occurred in either of these series, attesting to the safety of the procedure. Malthaner and Pearson reported the long-term clinical results in 35 patients with achalasia, having a minimum follow-up of 10 years (Table 25-10). Twenty-two of these patients underwent primary esophageal myotomy and Belsey hemifundoplication at the Toronto General Hospital. Excellent to good results were noted in 95% of patients at 1 year, declining to 68%, 69%, and 67% at 10, 15, and 20 years, respectively. Two patients underwent early reoperation for an incomplete myotomy, and three underwent an esophagectomy for progressive disease. They concluded that there was a deterioration of the initially good results after surgical myotomy and hiatal repair for achalasia, which is due to late complications of gastroesophageal reflux.

Ellis reported his lifetime experience with transthoracic short esophageal myotomy without an antireflux procedure. One hundred seventy-nine patients were analyzed at a mean follow-up of 9 years, ranging from 6 months to 20 years. Overall, 89% of patients were improved at the 9-year mark. He also observed that the level of improvement deteriorated with time, with excellent results (patients continuing to be symptom free) decreasing from 54% at 10 years to 32% at 20 years. He concluded that a short transthoracic myotomy without an antireflux procedure provides excellent long-term relief of dysphagia, and, contrary to Malthaner and Pearson’s experience, does not result in complications of gastroesophageal reflux. Both studies document nearly identical results 10 to 15 years following the procedure, and both report deterioration over time, probably due to progression of the underlying disease. The addition of an antireflux procedure if the operation is performed transthoracically has no significant effect on the outcome.

The outcome of laparoscopic myotomy and hemifundoplication has been well documented. Two reports of over

100 patients have documented relief of dysphagia in 93% of patients. Richter and coworkers reviewed published reports to date, including 254 patients with an average success rate of 93% at 2.5 years. Conversion to an open procedure occurs in 0% to 5% of patients. Complications are uncommon, occurring in <5% of patients. Intraoperative complications consist largely of mucosal perforation, and have been more likely to occur after botulinum toxin injection. The incidence of objective reflux disease as evidenced by abnormal acid exposure is <10%.

A number of randomized clinical trials in the past decade have compared the outcomes of laparoscopic Heller myotomy to pneumatic dilation and to botulinum toxin injection. In each of these trials, laparoscopic Heller myotomy and partial fundoplication was superior to the alternative treatment. Lastly, a randomized clinical trial examining the need for fundoplication following Heller myotomy demonstrated a great deal more reflux in patients without fundoplication, and no better swallowing in the Heller-only group. The best treatment for achalasia is a laparoscopic Heller myotomy and partial fundoplication. The role of POEM in the management of classic (nonspasitic) achalasia is yet to be established.

**Esophageal Resection for End-Stage Motor Disorders of the Esophagus**

Patients with dysphagia and long-standing benign disease, whose esophageal function has been destroyed by the disease process or multiple previous surgical procedures, are best managed by esophagectomy. Fibrosis of the esophagus and cardia can result in weak contractions and failure of the distal esophageal sphincter to relax. The loss of esophageal contractions can result in the stasis of food, esophageal dilatation, regurgitation, and aspiration. The presence of these abnormalities signals end-stage motor disease. In these situations esophageal replacement is usually required to establish normal alimentation. Before proceeding with esophageal resection for patients with end-stage benign disease, the choice of the organ to substitute for the esophagus (i.e., stomach, jejunum, or colon) should be considered. The choice of replacement is affected by a number of factors, as described later in the section on Techniques of Esophageal Reconstruction. If minimally invasive esophagectomy is to be performed, thoracoscopic dissection should be combined with abdominal dissection. Attempts at MIS transthoracic esophagectomy for the massively dilated esophagus may result in large volume bleeding from mediastinal vessels that become enlarged with esophageal dilation, and must be directly controlled for hemostasis to be adequate, and the operation to be safe.

**CARCINOMA OF THE ESOPHAGUS**

Squamous carcinoma accounts for the majority of esophageal carcinomas worldwide. Its incidence is highly variable, ranging from approximately 20 per 100,000 in the United States and Britain, to 160 per 100,000 in certain parts of South Africa and the Honan Province of China, and even 540 per 100,000 in the Guriev district of Kazakhstan. The environmental factors responsible for these localized high-incidence areas have not been conclusively identified, though additives to local foodstuffs (nitroso compounds in pickled vegetables and smoked meats) and mineral deficiencies (zinc and molybdenum) have been suggested. In Western societies, smoking and alcohol consumption are strongly linked with squamous carcinoma. Other definite associations link squamous carcinoma with longstanding achalasia, lye strictures, tylosis (an autosomal dominant disorder characterized by hyperkeratosis of the palms and soles), and human papillomavirus.

Adenocarcinoma of the esophagus, once an unusual malignancy, is diagnosed with increasing frequency (Fig. 25-66), and now accounts for more than 50% of esophageal cancer in most Western countries. The shift in the epidemiology of esophageal cancer from predominantly squamous carcinoma seen in association with smoking and alcohol, to adenocarcinoma in the setting of BE, is one of the most dramatic changes that have occurred in the history of human neoplasia. Although esophageal carcinoma is a relatively uncommon malignancy, its prevalence is exploding, largely secondary to the well-established association between gastroesophageal reflux, BE, and esophageal adenocarcinoma. Once a nearly uniformly lethal disease, survival has improved slightly because of advances in the understanding of its molecular biology, screening and surveillance practices, improved staging, minimally invasive surgical techniques, and neoadjuvant therapy.

Furthermore, the clinical picture of esophageal adenocarcinoma is changing. It now occurs not only considerably more frequently, but in younger patients, and is often detected at an earlier stage. These facts support rethinking the traditional approach of assuming palliation is appropriate in all patients. The historical focus on palliation of dysphagia in an elderly patient with comorbidities should change when dealing with a young patient with dependent children and a productive life ahead. The potential for cure becomes of paramount importance.

The gross appearance resembles that of squamous cell carcinoma. Microscopically, adenocarcinoma almost always originates in Barrett’s mucosa, and resembles gastric cancer. Rarely, it arises in the submucosal glands, and forms intramural growths that resemble the mucopidermal and adenoid cystic carcinomas of the salivary glands.

The most important etiologic factor in the development of primary adenocarcinoma of the esophagus is a metaplastic columnar-lined or Barrett’s esophagus, which occurs in approximately 10% to 15% of patients with GERD. When studied prospectively, the incidence of adenocarcinoma in a patient with BE is one in 100 to 200 patient-years of follow-up (i.e., for every 100 patients with BE followed for 1 year, one will develop adenocarcinoma). Although this risk appears to be small, it is at least 40 to 60 times that expected for a similar population without BE. This risk is similar to the risk for developing lung cancer in a person with a 20-pack-per-year history of smoking. Endoscopic surveillance for patients with BE is recommended for two reasons: (a) at present there is no reliable evidence that medical therapy removes the risk of neoplastic transformation, and (b) malignancy in BE is curable if detected at an early stage.

**Clinical Manifestations**

Esophageal cancer generally presents with dysphagia, although increasing numbers of relatively asymptomatic patients are now identified on surveillance endoscopy, or present with nonspecific upper GI symptoms and undergo screening endoscopy. Extension of the primary tumor into the tracheobronchial tree can occur primarily with squamous cell carcinoma and can cause stridor, tracheoesophageal fistula and resultant coughing, choking, and aspiration pneumonia. Rarely, severe bleeding from the primary tumor or from erosion into the aorta or pulmonary vessels occurs. Either vocal cord may
be invaded, causing paralysis, but most commonly, paralysis is caused by invasion of the left recurrent laryngeal nerve by the primary tumor or LN metastasis. Systemic organ metastases are usually manifested by jaundice or bone pain. The situation is different in high-incidence areas where screening is practiced. In these communities, the most prominent early symptom is pain on swallowing rough or dry food. In patients that present with back pain at the time of esophageal cancer diagnosis, there is usually distant metastasis or celiac encasement.

Dysphagia usually presents late in the natural history of the disease, because the lack of a serosal layer on the esophagus allows the smooth muscle to dilate with ease. As a result, the dysphagia becomes severe enough for the patient to seek medical advice only when more than 60% of the esophageal circumference is infiltrated with cancer. Consequently, the disease is usually advanced if symptoms herald its presence. Tracheoesophageal fistula may be present in some patients on their first visit to the hospital, and more than 40% will have evidence of distant metastases. With tumors of the cardia, anorexia and weight loss usually precede the onset of dysphagia. The physical signs of esophageal tumors are those associated with the presence of distant metastases.

**General Approach to Esophageal Cancer**

Therapy of esophageal cancer is dictated by the stage of the cancer at the time of diagnosis. Put simply, one needs to determine if the disease is confined to the esophagus, (T1–T2, N0), locally advanced (T1–3, N1), or disseminated (any T, any N, M1). If cancer is confined to the esophagus, removal of the tumor with adjacent lymph nodes may be curative. Very early tumors confined to the mucosa (T in situ, T1a, intramucosal cancer) may be addressed with endoscopic treatment. When the tumor is locally aggressive, modern therapy dictates a multimodality approach in a surgically fit patient. Multimodality therapy is either chemotherapy followed by surgery or radiation and chemotherapy followed by surgery. When given before surgery, these treatments are referred to as neoadjuvant or induction therapy. For disseminated cancer, treatment is aimed at palliation of symptoms. If the patient has dysphagia, as many do, the most rapid form of palliation is the endoscopic placement of an expandable esophageal stent. For palliation of GEJ cancer, radiation may be the first choice, as stents placed across the GEJ create a great deal of gastroesophageal reflux.

**Staging of Esophageal Cancer**

Choosing the best therapy for an individual patient requires accurate staging. Staging starts with the history and physical. LN disease remote from the tumor, particularly in the cervical region, may be palpable on neck examination and generally indicates cancer dissemination. This is often referred to as M1a disease, indicating that these patients should not be treated with therapy directed toward locally advanced cancer. Other metastatic LNs are rarely palpable but are equally ominous, especially the umbilical LN in GEJ cancer.

Computed tomographic (CT) scanning of the chest, abdomen, and pelvis provides information on local invasion of the primary cancer, LN involvement, or disseminated disease. The most common sites of esophageal cancer metastases are lung, liver, and peritoneal surfaces, including the omentum and small bowel mesentery. If masses are identified that are not characteristic for cancer or are in a location that precludes resection with the cancer specimen, positron emission tomography (PET) scanning may be utilized. PET scanning can detect most tumors, including those that are occult on CT scanning. PET scanning is most useful in the assessment of locoregional disease, as well as for monitoring the response of patients treated with chemotherapy. The PET scan is also useful in staging chest and abdominal lymph nodes and bone.

**Figure 25-66.** Incidence and mortality rate trends for esophageal cancer. NCI = National Cancer Institute. (Reproduced with permission from the National Cancer Institute. Last updated September, 2008.)
(PET) scanning may be able to tell whether the masses are metabolically active (likely to be cancer) or not. A PET active focus corresponding to a mass on CT scan outside of the field of esophageal resection should be biopsied before resection is performed.

The introduction of endoscopic ultrasound (EUS) has made it possible to identify patients who are potentially curable before surgical therapy. Using an endoscope, the depth of the wall penetration by the tumor and the presence of LN metastases can be determined with 80% accuracy. A curative resection should be encouraged if EUS indicates that the tumor has not invaded adjacent organs (T4b), and/or fewer than six enlarged LNs are imaged. Thoracoscopic and laparoscopic staging of esophageal cancer may add benefit when the nature of enlarged LNs remote from the cancer cannot be determined, or when advanced imaging systems (PET and high-resolution spiral CT) are not available.

Occasionally, diagnostic laparoscopy and jejunostomy tube placement may precede induction chemotherapy in the patient with severe dysphagia and weight loss from a locally advanced cancer. In summary, esophageal cancer is diagnosed with endoscopic biopsy and is staged with CT scanning of the chest and abdomen, EUS, and PET scan for all patients with CT or EUS evidence of advanced disease (T2 or greater, N1-2 or NX). Experience with esophageal resection in patients with early stage disease has identified characteristics of esophageal cancer that are associated with improved survival. A number of studies suggest that only metastasis to LNs and tumor penetration of the esophageal wall have a significant and independent influence on prognosis. Factors known to be important in the survival of patients with advanced disease, such as cell type, degree of cellular differentiation, or location of tumor in the esophagus, have no effect on survival of patients who have undergone resection for early disease. Studies also showed that patients having five or fewer LN metastases have a better outcome. Using these data, Skinner developed the wall penetration, LN, and distant organ metastases system for staging.

The wall penetration, LN, and distant organ metastases system differed somewhat from the previous efforts to develop a satisfactory staging criteria for carcinoma of the esophagus. Most surgeons agreed that the 1983 tumor, nodes, and metastasis system left much to be desired. In the third edition of the manual for Staging of Cancer of the American Joint Committee on Cancer (AJCC) in 1988, an effort was made to provide a finer discrimination between stages than had been contained in the previous edition in 1983. In 2010, further refinements of the staging system of esophageal cancer were approved by the AJCC, recognizing the difference in survival afforded by resection of limited LN disease adjacent to the tumor, compared to multilevel LN disease and positive LNs remote from the primary tumor. Table 25-11 shows the AJCC definitions for the primary tumor, lymph nodes, distant metastasis, and overall staging schema for both squamous cell carcinoma and adenocarcinoma.

**Clinical Approach to Carcinoma of the Esophagus and Cardia**

The selection of a curative vs. a palliative operation for cancer of the esophagus is based on the location of the tumor, the patient’s age and health, the extent of the disease, and preoperative staging. Figure 25-67 shows an algorithm of the clinical decisions important in the selection of curative or palliative therapy.

**Tumor Location.** The selection of surgical therapy for patients with carcinoma of the esophagus depends not only on the anatomic stage of the disease and an assessment of the swallowing capacity of the patient, but also on the location of the primary tumor.

It is estimated that 8% of the primary malignant tumors of the esophagus occur in the cervical portion (Fig. 25-68). They are almost always squamous cell cancer, with a rare adenocarcinoma arising from a congenital inlet patch of columnar lining. These tumors, particularly those in the postcricoid area, represent a separate pathologic entity for two reasons: (a) They are more common in females and appear to be a unique entity in this regard; and (b) The effenter lymphatics from the cervical esophagus drain completely differently from those of the thoracic esophagus. The latter drain directly into the paratracheal and deep cervical or internal jugular LNs with minimal flow in a longitudinal direction. Except in advanced disease, it is unusual for intrathoracic LNs to be involved.

Cervical esophageal cancer is frequently unresectable because of early invasion of the larynx, great vessels, or trachea. Radical surgery, including esophagolaryngectomy may occasionally be performed for these lesions, but the ensuing morbidity makes this a less than desirable approach in the face of uncertain cure. Thus, for most patients with cervical esophageal cancer, stereotactic radiation with concomitant chemotherapy is the most desirable treatment.

Tumors that arise within the middle third of the esophagus are squamous carcinomas most commonly and are frequently associated with LN metastasis, which are usually in the thorax but may be in the neck or abdomen, and may skip areas in between. Although it is generally felt that individuals with midthoracic cancer and abdominal LN metastases are incurable with surgery, there are some emerging data that suggest that cervical LN metastases, if isolated, can be resected with benefit. Generally, T1 and T2 cancers without LN metastases are treated with resection only, but there is more and more data to suggest that LN involvement or transmural cancer (T3) warrants treatment with neoadjuvant chemoradiation therapy followed by resection. Although some surgeons prefer a transhiatal esophagectomy for all tumor locations, most surgeons believe that resection of midesophageal cancer should be performed under direct vision with either thoracoscopy (video-assisted thoracic surgery [VATS]) or with thoracotomy.

Tumors of the lower esophagus and cardia are usually adenocarcinomas. Unless preoperative and intraoperative staging clearly demonstrate an incurable lesion, resection in continuity with a LN dissection should be performed. Because of the propensity of GI tumors to spread for long distances submucosally, long lengths of grossly normal GI tract should be resected. The longitudinal lymph flow in the esophagus can result in skip areas, with small foci of tumor above the primary lesion, which underscores the importance of a wide resection of esophageal tumors. Wong has shown that local recurrence at the anastomosis can be prevented by obtaining a 10-cm margin of normal esophagus above the tumor. Anatomically, tumors have also shown that there is no submucosal lymphatic barrier between the esophagus and the stomach at the cardia, and Wong has shown that 50% of the local recurrences in patients with esophageal cancer who are resected for cure occur in the intrathoracic stomach along the line of the gastric resection. Considering that the length of the esophagus ranges from 17 to 25 cm, and the length of the lesser curvature of the stomach is approximately 12 cm, a curative resection requires a cervical division of the esophagus and a >50% proximal gastrectomy in most patients with carcinoma of the distal esophagus or cardia.

ADENOCARCINOMA

Age. Resection for cure of carcinoma of the esophagus in a patient older than 80 years is rarely indicated, because of the additional operative risk and the shorter life expectancy. Despite this general guideline, octogenarians with a high performance status and excellent cardio-pulmonary reserve may be considered candidates for esophagectomy and recent case series have established its success in highly selected patients. It is in this group of patients that the lesser physiologic impact of minimally invasive surgery may reduce the morbidity and mortality associated with open two- or three-field esophagectomy.

Cardiopulmonary Reserve. Patients undergoing esophageal resection should have sufficient cardiopulmonary reserve to tolerate the proposed procedure. The respiratory function is best assessed with the forced expiratory volume in 1 second, which ideally should be 2 L or more. Any patient with a forced expiratory volume in 1 second of <1.25 L is a poor candidate for thoracotomy, because he or she has a 40% risk of dying from respiratory insufficiency within 4 years. In patients with poor pulmonary reserve, the transhiatal esophagectomy should be considered, as the pulmonary morbidity of this operation is less than is seen following thoracotomy. Clinical evaluation and electrocardiogram are not sufficient indicators of cardiac reserve. Echocardiography and dipyridamole thallium imaging provide accurate information on wall motion, ejection fraction, and myocardial blood flow. A defect on thallium imaging may require further evaluation with preoperative coronary angiography. A resting ejection fraction of <40%, particularly if there is no increase with exercise, is an ominous sign. In the absence of invasive testing, observed stair-climbing is an economical (albeit not quantitative) method of assessing cardiopulmonary reserve. Most individuals who can climb three flights of stairs without stopping will do well with two-field open esophagectomy, especially if an epidural catheter is used for postoperative pain relief.

Nutritional Status. The factor most predictive of postoperative complication is the nutritional status of the patient. Profound weight loss, more than 20 lb, associated with hypoalbuminemia (albumin <3.5 g/dL) is associated with a much higher rate of complications and mortality than patients who enter curative

**Figure 25-68.** Incidence of carcinoma of the esophagus and cardia based on tumor location.
surgery in better nutritional condition. Because malnourished patients generally have locally advanced esophageal cancer, if not metastatic disease, one should consider the placement of a feeding tube before the beginning of induction chemoradiation therapy. Although mild amounts of dysphagia are improved by induction chemoradiation therapy, more pronounced dysphagia and associated malnutrition should be addressed before the initiation of chemoradiation. A laparoscopic jejunostomy tube can be placed prior to induction therapy or at the time of esophagectomy. There are emerging data that 5 days’ pretreatment with immune-enhancing nutrition, rich in fish oils, decreases cardiac and other complications, following esophagectomy.

Clinical Staging. Clinical factors that indicate an advanced stage of carcinoma and exclude surgery with curative intent are recurrent nerve paralysis, Horner’s syndrome, persistent spinal pain, paralysis of the diaphragm, fistula formation, and malignant pleural effusion. Factors that make surgical cure unlikely include a tumor >8 cm in length, abnormal axis of the esophagus on a barium radiogram, more than four enlarged LNs on CT, a weight loss more than 20%, and loss of appetite. Studies indicate that there are several favorable parameters associated with tumors <4 cm in length, there are fewer with tumors between 4 and 8 cm, and there are no favorable criteria for tumors >8 cm in length. Consequently, the finding of a tumor >8 cm in length should exclude curative resection; the finding of a smaller tumor should encourage an aggressive approach.

Preoperative Staging with Advanced Imaging. For years, clinical staging, contrast radiography, endoscopy, and CT scanning formed the backbone of esophageal cancer staging. More recently, preoperative decision making is guided by endoscopic ultrasonography and PET scanning.

EUS provides the most reliable method of determining depth of cancer invasion. In the absence of enlarged LNs, the degree of wall invasion dictates surgical therapy. If a small focus of esophageal cancer is confined to the mucosa, endoscopic mucosal resection (EMR) is a preferable option. If the tumor invades in to the submucosa, without visible lymph node involvement, most individuals would suggest esophagectomy with LN dissection, as positive nodes can be found in 20% to 25% of those with cancer limited to the mucosa and submucosa. If EUS demonstrates spread through the wall of the esophagus, especially if LNs are enlarged, then induction chemoradiation therapy (neoadjuvant therapy) should be strongly considered. Lastly, when the EUS demonstrates invasion of the trachea, bronchus, aorta, or spine, then surgical resection is rarely indicated. If there is invasion into the pleura (T4a), then surgical resection can be considered in the absence of a malignant effusion. Thus, it can be seen that the therapy of esophageal cancer is largely driven by the findings of endoscopic ultrasonography. It is difficult to provide modern treatment of esophageal cancer without access to this modality.

PET scanning, usually combined with an axial CT scan (CTPET), is usually performed on patients with locally advanced cancer or questionable lesions on CT scan to determine whether metastases are present. The PET scan uses the injection of radiolabeled deoxyglucose, which is taken up in metabolically active tissues such as cancer. PET-positive areas must be correlated with the CT scan findings to assess the significance of “hot spots.” CTPET scanning has been especially useful before the initiation of chemoradiation therapy. An early response to chemoradiotherapy, by PET scan, improves the prognosis whether or not resection is ultimately performed. Conversely, if a PET-avid tumor shows no change in metabolic activity after 2 weeks of induction chemoradiation therapy, it is unlikely that further chemoradiation or radiation therapy will be of any benefit. These patients have a worse prognosis, and may be referred for resection or palliation without incurring the morbidity or expense of a full course of chemoradiation therapy.

Palliation of Esophageal Cancer

Palliation of esophageal cancer is indicated for individuals with metastatic esophageal cancer or cancer invading adjacent organs (T4b) who are unable to swallow, or individuals with fistulae into the tracheobronchial tree. Aortic esophageal fistulas are extremely rare and nearly 100% lethal. Dysphagia as a result of esophageal cancer can be graded from Grade I, eating normally, to grade VI, unable to swallow saliva (Table 25-12). Grades I–III often can be managed with radiation therapy, usually in combination with chemotherapy. When surgical resection is not anticipated in the future, this is termed definitive chemoradiation therapy and usually is palliative. Radiation dose is increased from 45 Gy to 60 Gy administered over 8 weeks, rather than the 4 weeks given for chemoradiation induction therapy. In 20% of patients, a complete response to chemoradiation therapy will not only palliate the symptoms, but leave the patient with undetectable cancer of the esophagus. Although some of these patients are truly cured, cancer will recur in many either locally or systematically 1 to 5 years following definitive chemoradiation. In a few patients, definitive chemoradiation will be successful in all sites but the esophagus. After a 12-month wait from initial treatment and no other sites of tumor detectable except the esophagus, some of these patients may be candidates for salvage esophagectomy.

For individuals with dysphagia grades IV and higher, additional treatment generally is necessary. The mainstay of therapy is in-dwelling esophageal stents. Covered removable stents may be used to seal fistulae or when stent removal becomes desirable in the future. When large, locally invasive tumors or metastatic esophageal cancer preclude any future hope of resection, uncovered expandable metal stents are the treatment of choice. The major limitations to stenting exist in cancers at the GEJ. A stent placed across the GEJ will result in severe gastroesophageal

reflux and heartburn that can be quite disabling. In cancers at this level, radiation therapy alone may be preferable. If feeding access is desirable, a laparoscopic jejunostomy is usually the procedure of choice.

**Surgical Treatment**

The surgical treatment of esophageal cancer is dependent upon the location of the cancer, the depth of invasion, LN metastases, the fitness of the patient for operation, and the culture and beliefs of the individuals and institutions in which the treatment is performed. In an ideal world, there would be a single, stage-specific method of treating esophageal cancer, because the evidence would be unassailable and noncontroversial. Randomized clinical trials and meta-analyses would prove beyond a shadow of a doubt the value of surgery vs. nonoperative therapy and would dictate the type and extent of surgery that would optimally balance immediate morbidity and mortality with duration and quality of life conferred by the procedure and the perioperative management of the esophagectomy patient. Despite many noble attempts to establish this high level of evidence, many questions relating to the appropriate therapy of esophageal cancer remain controversial. About the only area of complete agreement is that esophagectomy should not be performed if an R0 resection is not possible. In other words, if the surgeon does not believe he or she can remove all LN invaded by cancer and provide a tumor-free radial margin and esophagus and stomach margins that are tumor free, then a resection should not be performed.

**Mucosally Based Cancer.** In patients with BE, and especially those with high-grade dysplasia, subcentimeter nodules are frequently discovered. Nodules should be resected in entirety, as they often harbor adenocarcinoma. Five years ago, such resection was performed with a transhiatal esophagectomy, but more recently EMR offers another method for removing intramucosal cancer. In this clinical situation, EMR is typically combined with EUS to rule out more invasive disease. EUS however, is unable to differentiate between cancer that is confined to the mucosa (T1a) and that which invades the submucosa (T1b). Tumors invading the submucosa are not amenable to endoscopic mucosal resection because of the high-frequency (20%–25%) concurrent finding of positive LN, which cannot be removed without esophagectomy. On the other hand, intramucosal cancers have little risk of spreading to regional LN. The current approach used involves performing EMR on all nodules identified in a field of Barrett’s esophagus and then T staging is performed by histologic analysis. This approach dictates the need for future therapy such as esophagectomy.

For this reason, small intramucosal carcinomas may be removed with EMR in the following manner. The area beneath the nodule is infiltrated with saline through a sclerotherapy needle. A specialized suction cap is mounted on the end of the endoscope and the nodule is drawn up into the cap, following which a snare is applied to resect the tissue. Alternatively, a rubber band can be delivered and the snare can be used to resect above the level of the rubber band. This specimen is then removed and sent to pathology. As long as the tumor is found to be confined to the mucosa and all margins are negative, the resection is complete. A positive margin or involvement of the submucosa warrants esophagectomy. Most importantly, these patients are at high risk for developing small nodular carcinomas elsewhere in their Barrett’s segment, and routine surveillance on a 3- to 6-month basis must be continued indefinitely. Alternatively, one can consider radiofrequency ablation of the remainder of the high-grade dysplasia after careful surveillance biopsy specimens demonstrate no further sign of cancer. This approach to the early esophageal cancer should not be used when there is any suspicion of mediastinal or abdominal lymphadenopathy. Although it is currently rare that EMR provides definitive therapy of small nodular esophageal cancers, this may become more of the norm as greater surveillance reveals earlier cancers, and proficiency of the technique by surgeons and gastroenterologists increases.

**Minimally Invasive Transhiatal Esophagectomy.** Minimally invasive transhiatal esophagectomy is an increasingly popular procedure; however, the number of these operations performed around the world remains small. Mini-invasive surgery (MIS) transhiatal esophagectomy was first performed by Aureo DePaula in Brazil and has been modified and adopted by many individuals around the world. This operation combines the advantages of transhiatal esophagectomy at minimizing pulmonary complications with the advantages of laparoscopy (less pain, quicker rehabilitation). Several variations of MIS transhiatal esophagectomy have been developed. For the earliest lesions, such as high-grade dysplasia or intramucosal carcinoma, a vagal sparing procedure can be entertained. In such a procedure, the vagal trunks are separated from the esophagus at the level of the diaphragm and the lesser curvature dissection of the stomach allows the vagus and left gastric pedicle to remain intact. Clearly, this dissection, which hugs the stomach and esophagus, provides no LN staging and is thus inadequate for all high-grade dysplasia and intramucosal cancer.

MIS transhiatal esophagectomy is usually performed through five or six small incisions in the upper abdomen and a transverse cervical incision for removing the specimen and performing the cervical esophagogastrectomy. To remove the esophagus from the posterior mediastinum, especially the area behind the pulmonary vessels and the tracheal bifurcation, which cannot be visualized even with a long laparoscope placed in the posterior mediastinum, it is preferred to use a vein stripping “inversion” technique (Fig. 25-69A). The details of this operation are too lengthy to include in this text, but include the laparoscopic creation of a neo-esophagus (gastric conduit) along the greater curvature of the stomach using the right gastroepiploic artery as the primary vascular pedicle. The conduit can be created through a mini-laparotomy or laparoscopically. A Kocher maneuver releases the duodenum, and a pyloroplasty may be performed (optional). Retrograde esophageal stripping is performed by dividing the esophagus below the GEJ and sliding a vein stripper from the neck down into the abdomen followed by an inversion of the esophagus in the posterior mediastinum and removal through the neck (Fig. 25-69B). This technique is reserved for patients with high-grade dysplasia. For small cancers at the GEJ, the esophagus can be stripped in an antegrade fashion by sliding the vein stripper down from the cervical incision and out the tail of the lesser curvature (Fig. 25-69C). The tail of the lesser curvature is pulled out a port site high in the epigastrium while the esophagus is inverted into itself. For GEJ cancers, a wide celiac access LN dissection, splenic artery, hepatic artery, and posterior mediastinal LN dissection can be performed as well or better than through a laparotomy. The gastric conduit is pulled up to the neck with a chest tube and anastomosed to the cervical esophagus in an end-to-side fashion using a surgical stapler or with a handsewn anastomosis. Complications of this technique are primarily limited to leak from the
esophagogastric anastomosis, which is self-limited and usually heals within 1 to 3 weeks, spontaneously.

**Open Transhiatal Esophagectomy.** Transhiatal esophagectomy, also known as blunt esophagectomy or esophagectomy without a thoracotomy, was first performed in 1933 by a British surgeon, but was popularized in the last quarter of the twentieth century by Mark Orringer from the University of Michigan. Although this operation may violate many of the principles of cancer resection, including extended radical LN dissection this operation has performed as well as any of the more radical procedures in randomized trials, and in large database analyses. With transhiatal esophagectomy, the elements of dissection are similar to that described in the section entitled Minimally Invasive Transhiatal Esophagectomy, including the creation of the gastric tube and the posterior mediastinal dissection through the hiatus. Because this dissection is performed with the fingertips rather than under direct vision with surgical instruments, it requires an enlargement of the diaphragmatic hiatus. The lower mediastinal LN basins can be resected as can the upper abdominal LNs, making this an attractive option for GEJ cancers. The mediastinal LNs above the inferior pulmonary vein are not removed with this technique, but rarely result in a point of isolated cancer recurrence.

Of all procedures for esophageal cancer, this operation is the quickest to perform in experienced hands and lies in an intermediate position between minimally invasive esophagectomy and the Ivor Lewis procedure with respect to complications and recovery.

**Minimally Invasive Two- and Three-Field Esophagectomy.** After a rocky start, minimally invasive esophagectomy using a thoracic dissection through VATS has become reasonably popular. In general, this operation is performed with an anastomosis created in the neck (three-field), but may be performed with the anastomosis stapled in the high thorax (two-field). Both procedures will be described.

With a minimally invasive three-field esophagectomy, the patient is placed in the left lateral decubitus position. Double lumen intubation is required. Videoscopic access to the thorax is obtained in the midaxillary line in the ninth intercostal space and an angled telescope illuminates the chest superiorly. A minithoracotomy at about the sixth intercostal space anteriorly allows introduction of conventional surgical instruments, and a high trocar allows retraction of the lung away from the esophagus. In a three-field approach, the esophagus is dissected along its length to include division of the azygos vein and harvesting of the LNs in the upper, middle, and lower posterior mediastinum. Hilar, and posterior mediastinal nodes are all removed and sent with the specimen or individually. The thoracic duct is divided at the level of the diaphragm and removed with the specimen.

Following complete intrathoracic dissection, the patient is placed in the supine position and five laparoscopic ports are placed as with the MIS transhiatal esophagectomy. The abdominal portions of the operation are identical to those described previously in the section entitled Minimally Invasive Transhiatal Esophagectomy, and the gastric conduit is then sewn to the tip of the fully mobilized GEJ and lesser curvature sleeve. A feeding tube is placed and the pyloroplasty may be performed laparoscopically. A transverse cervical incision and dissection between the sternocleidomastoid and the anterior strap muscles allows access to the cervical esophagus. Great care is made to avoid stretching the recurrent laryngeal nerve. The esophagus

---

**Figure 25-69.** A. Laparoscopic retrograde inversion. B. Laparoscopic antegrade inversion. A silk suture holds the tunnel after the esophagus is removed. C. The esophageal conduit is returned to the neck after passing a chest tube down the tunnel and suturing the conduit to the chest tube.
and proximal stomach is then pulled up into the neck with the gastric conduit following. Cervical anastomosis is then performed.

The MIS transthoracic two-field esophagectomy is slightly different. In this operation, the abdominal portions of the operation are done first, including placement of the feeding tube, the creation of the conduit, and the sewing of the tip of the conduit to the fully dissected GEJ. The patient is then rolled into the left lateral decubitus position and, through right thoracoscopy, the esophagus is dissected and divided 10 cm above the tumor. Once freed, the specimen is pulled out through the mini-thoracotomy and an end-to-end anastomosis stapler is introduced through the high corner of the gastric conduit out a stab wound along the greater curvature. The anvil of the stapler is placed in the proximal esophagus and held with a purse-string; the stapler is docked, the anastomosis is created, and a gastrostomy is then closed with another firing of the GIA stapler. The three-field esophagectomy has the advantage of placing the anastomosis in the neck where leakage is unlikely to create a severe systemic consequence. On the other hand, placement of the anastomosis in the high chest minimizes the risks of injury to structures in the neck, particularly the recurrent laryngeal nerve. Although the leak of the intrathoracic anastomosis may be more likely to bear septic consequences, the incidence of leak is diminished. Other complications of this approach relate to pulmonary and cardiac status. In many series, the most common complication is pneumonia, the second is atrial fibrillation, and the third is anastomotic leak.

Ivor Lewis (En Bloc) Esophagectomy. The theory behind radical transthoracic esophagectomy is that greater removal of LNs and peri-esophageal tissues diminishes the chance of a positive radial margin and LN recurrence. Although there are no randomized data demonstrating this to be superior to other forms of esophagectomy, there are many retrospective data demonstrating improved survival with greater numbers of LNs harvested. A recent study from Sloan-Kettering demonstrates a direct relationship between the number of negative nodes harvested and long-term survival. Although such a survival advantage may be related to the completeness of resection, extended radical resections may also be a surrogate for experienced surgeons working in great institutions. As a time-honored operation, there is no doubt that en bloc esophagectomy is the standard to which less radical techniques must be compared.

Generally, this operation is started in the abdomen with an upper midline laparotomy and extensive LN dissection in and about the celiac access and its branches, extending into the porta hepatitis and along the splenic artery to the tail of the pancreas. All LNs are removed en bloc with the lesser curvature of the stomach. Unless the tumor extends into the stomach, reconstruction is performed with a greater curvature gastric tube. For GEJ cancers extending significantly into the gastric cardia or fundus, the proximal stomach is removed and reconstruction is performed with an isoperistaltic section of left colon between the upper esophagus and the remnant stomach, or the colon is connected to a Roux-en-Y limb of jejunum, if total gastrectomy is necessary. In the majority of cases, colon interposition is unnecessary, and a gastric conduit is used.

Following closure of the abdominal incision, the patient is placed in the left lateral decubitus position and an anterolateral thoracotomy is performed through the sixth intercostal space. The azygos vein is divided and the posterior mediastinum is entirely cleaned out to include the thoracic duct, all periaortic tissues, and all tissue in the upper mediastinum along the course of the current laryngeal nerves and in the peri-bronchial, hilar, and tracheal LN stations. The proximal stomach is pulled up into the thorax where a conduit is created (if not performed previously) and a handsewn or stapled anastomosis is made between the upper thoracic esophagus and the gastric conduit or transverse colon. Chest tubes are placed, and the patient is taken to the intensive care unit.

Because this is the most radical of dissections, complications are most common, including pneumonia, respiratory failure, atrial fibrillation, chylothorax, anastomotic leak, conduit necrosis, gastrocutaneous fistula, and, if dissection is too near the recurrent laryngeal nerves, hoarseness will occur with an increased risk of aspiration. Tracheobronchial injury resulting in fistulas between the bronchus and conduit may also occur, however rarely. Although this procedure and three-field esophagectomy are fraught with the highest complication rate, the long-term outcome of this procedure provides the greatest survival in many single-center series and retrospective reviews.

Three-Field Open Esophagectomy. Three-field open esophagectomy is very similar to a minimally invasive three-field except that all access is through open incisions. This procedure is performed by certain Japanese surgeons and LN counts achieved through this kind of operation may run from 45 to 60 LNs. Most Western surgeons question the benefit of such radical surgery when it is hard to define a survival advantage. Nonetheless, high intrathoracic cancers probably deserve such an aggressive approach if cure is the goal.

Salvage Esophagectomy. Salvage esophagectomy is the nomenclature applied to esophagectomy performed after failure of definitive radiation and chemotherapy. The most frequent scenario is one in which distant disease (bone, lung, brain, or wide LN metastases) renders the patient nonoperable at initial presentation. Then, systemic chemotherapy, usually with radiation of the primary tumor, destroys all foci of metastasis, as demonstrated by CT and CT-PET, but the primary remains present and symptomatic. Following a period of observation, to make sure no new disease will become evident, salvage esophagectomy is performed, usually with an open two-field approach. Surprisingly, the cure rate of salvage esophagectomy is not inconsequential. One in four patients undergoing this operation will be disease free 5 years later, despite the presence of residual cancer in the operative specimen. Because of the dense scarring created by radiation treatment, this procedure is the most technically challenging of all esophagectomy techniques.

Comparative Studies of Esophagectomy Technique

Transhoracic vs. Transhiatal Esophagectomy. There has been a great debate as to whether en bloc esophagectomy will provide a greater long-term benefit and cure rate in esophageal cancer than transhiatal esophagectomy. In a recent 7-year follow-up of a Dutch study addressing GEJ and lower esophageal cancers, there does not appear to be any benefit to the more extensive dissection despite higher morbidity and mortality. In a subgroup analysis of those with one to eight positive LNs, it did appear that the en bloc transthoracic resection may add to longevity. In another large database analysis of the Surveillance, Epidemiology, and End Results database, transthoracic and transhiatal esophagectomy were compared. In this study,
the transhiatal esophagectomy had a greater long-term survival, but, when adjusted by cancer stage, this survival benefit disappeared. The mortality and morbidity after transhiatal esophagectomy appeared to be less. Suffice it to say that this debate over the best procedure for esophagectomy remains an open question.

The role of the minimally invasive surgical procedures for a cancer cure will require further study and longer follow-up. It would appear from preliminary analysis that the transhiatal esophagectomy, like its open cousin, may be performed with less morbidity and mortality than the VATS procedure. Long-term survival analyses will require careful follow-up for at least 5 to 10 years after cancer treatment. A recent European multicenter randomized trial comparing open and minimally invasive procedures revealed a highly significant reduction in pulmonary complications in the patients who underwent the minimally invasive approach. There was no difference in procedure-related mortality between the approaches.

**Alternative Therapies**

**Radiation Therapy.** Primary treatment with radiation therapy does not produce results comparable with those obtained with surgery. Currently, the use of radiotherapy is restricted to patients who are not candidates for surgery, and is usually combined with chemotherapy. Radiation alone is used for palliation of dysphagia but the benefit is short lived, lasting only 2 to 3 months. Furthermore, the length and course of treatment are difficult to justify in patients with a limited life expectancy. Radiation is effective in patients who have hemorrhage from the primary tumor.

**Adjuvant Chemotherapy.** The proposal to use adjuvant chemotherapy in the treatment of esophageal cancer began when it became evident that most patients develop postoperative systemic metastasis without local recurrence. This observation led to the hypothesis that undetected systemic micrometastasis had been present at the time of diagnosis, and, if effective systemic therapy was added to local regional therapy, survival should improve.

Recently, this hypothesis has been supported by the observation of epithelial tumor cells in the bone marrow in 37% of patients with esophageal cancer who were resected for cure. These patients had a greater prevalence of relapse at 9 months after surgery compared to those patients without such cells. Such studies emphasize that hematogenous dissemination of viable malignant cells occurs early in the disease, and that systemic chemotherapy may be helpful if the cells are sensitive to the agent. On the other hand, systemic chemotherapy may be a hindrance, because of its immunosuppressive properties, if the cells are resistant. Unfortunately, current technology is not able to test tumor cell sensitivity to chemotherapeutic drugs. This requires that the choice of drugs be made solely on the basis of their clinical effectiveness against grossly similar tumors.

The decision to use preoperative rather than postoperative chemotherapy was based on the ineffectiveness of chemotherapeutic agents when used after surgery, and animal studies suggesting that agents given before surgery were more effective. The claim that patients who receive chemotherapy before resection are less likely to develop resistance to the drugs is unsupported by hard evidence. The claim that drug delivery is enhanced because blood flow is more robust before patients undergo surgical dissection is similarly flawed, due to the fact that if enough blood reaches the operative site to heal the wound or anastomosis, then the flow should be sufficient to deliver chemotherapeutic drugs. There are, however, data supporting the claim that preoperative chemotherapy in patients with esophageal carcinoma can, if effective, facilitate surgical resection by reducing the size of the tumor. This is particularly beneficial in the case of squamous cell tumors above the level of the carina. Reducing the size of the tumor may provide a safer margin between the tumor and the trachea, and allow an anastomosis to a tumor-free cervical esophagus just below the cricopharyngeus. Involved margin at this level usually requires a laryngectomy to prevent subsequent local recurrence.

**Preoperative Chemotherapy.** Eight randomized prospective studies of neoadjuvant chemotherapy vs. surgery alone have demonstrated mixed results. For adenocarcinomas of the distal esophagus and proximal stomach, preoperative neoadjuvant 5-fluorouracil (5-FU) and cisplatin chemotherapy has been shown to provide a survival advantage over surgery alone in a well-powered study from the United Kingdom (MRC trial). This trial is one of the few to include enough patients (800) to detect small differences. The trial had a 10% absolute survival benefit at 2 years for the neoadjuvant chemotherapy group. In a second trial from the United Kingdom (MAGIC trial) of distal esophageal and proximal gastric adenocarcinomas, the use of etoposide in combination with cisplatin and 5-FU also demonstrated a survival advantage for the induction chemotherapy arm with 4 years median follow-up. As a result of these two trials, standard treatment of locally advanced adenocarcinoma in Europe calls for neoadjuvant chemotherapy with one of these two regimens. Most failures are due to distant metastatic disease, underscoring the need for improved systemic therapy. Postoperative septic and respiratory complications may be more common in patients receiving chemotherapy.

**Preoperative Combination Chemo- and Radiotherapy.** Preoperative chemoradiotherapy using cisplatin and 5-FU in combination with radiotherapy has been reported by several investigators to be beneficial in both adenocarcinoma and squamous cell carcinoma of the esophagus. There have been 10 randomized prospective studies (Table 25-13). A recent meta-analysis of these trials demonstrates a 13% survival advantage for neoadjuvant chemoradiation therapy, which is more pronounced for patients with adenocarcinoma than for those with squamous carcinoma (Table 25-14). It was also observed that the benefit for chemotherapy alone (7%) was not as dramatic as for chemoradiotherapy used in the neoadjuvant setting. Additionally, other work has demonstrated the importance of obtaining an R0 (tumor-free) resection as the most important variable determining long-term survival. Although there are not direct, randomized comparisons between chemotherapy and chemoradiation therapy, it appears that the addition of radiation may improve local control of the tumor, and may allow a greater opportunity for the surgeon to obtain an R0 resection.

The timing of surgery after chemoradiation induction is generally felt to be optimal between 6 and 8 weeks following the completion of induction therapy. Earlier than this time, active inflammation may make the resection hazardous, and the patients have not had time to recover fully from the chemoradiation. After 8 weeks, edema in the periesophageal tissue starts to turn to scar tissue, making dissection more difficult.

With chemoradiation, the complete response rates for adenocarcinoma range from 17% to 24% (Table 25-15). No tumor

is detected in the specimen after esophagectomy. Patients demonstrating a complete response to chemoradiation have a better survival rate than those without complete response, but distant failure remains common.

At present, the strongest predictors of outcome of patients with esophageal cancer are the anatomic extent of the tumor at diagnosis and the completeness of tumor removal by surgical resection. After incomplete resection of an esophageal cancer, the 5-year survival rates are 0% to 5%. In contrast, after complete resection, independent of stage of disease, 5-year survival ranges from 15% to 40%, according to selection criteria and stage distribution. The importance of early recognition and adequate surgical resection cannot be overemphasized. Figure 25-70 is a global algorithm for the management of esophageal carcinoma.

SARCOMA OF THE ESOPHAGUS

Sarcomas and carcinosarcomas are rare neoplasms, accounting for approximately 0.1% to 1.5% of all esophageal tumors. They present with the symptom of dysphagia, which does not differ from the dysphagia associated with the more common epithelial carcinoma. Tumors located within the cervical or high thoracic esophagus can cause symptoms of pulmonary aspiration secondary to esophageal obstruction. Large tumors originating at the level of the tracheal bifurcation can produce symptoms of airway obstruction and syncope by direct compression of the tracheobronchial tree and heart (Fig. 25-71). The duration of dysphagia and age of the patients affected with these tumors are similar to those with carcinoma of the esophagus.

A = doxorubicin; E = etoposide; 5-FU = 5-fluorouracil; MGH = Massachusetts General Hospital; P = cisplatin; RT = radiation therapy; SLMC = St. Louis University Medical Center; VBL = vinblastine.

A barium swallow usually shows a large polypoid intraluminal esophageal mass, causing partial obstruction and dilatation of the esophagus proximal to the tumor (Fig. 25-72). The smooth polypoid nature of the lesion, although not diagnostic, is distinctive enough to suggest the presence of a sarcoma rather than the more common ulcerating, stenosing carcinoma.

Endoscopy commonly shows an intraluminal necrotic mass. When biopsy is attempted, it is important to remove the necrotic tissue until bleeding is seen on the tumor’s surface. If this is not done, the biopsy specimen will show only tissue necrosis. Even when viable tumor is obtained on biopsy, it has been these authors’ experience that it cannot be definitively identified as carcinoma, sarcoma, or carcinosarcoma on the basis of the histology of the portion biopsied. Biopsy results cannot be totally relied on to identify the presence of sarcoma, and it is often the polypoid nature of the lesion that arouses suspicion that it may be something other than carcinoma.

Polypoid sarcomas of the esophagus, in contrast to infiltrating carcinomas, remain superficial to the muscularis propria and are less likely to metastasize to regional LNs. In one series of 14 patients, local extension or tumor metastasis would have prevented a potentially curative resection in only five. Thus, the presence of a large polypoid tumor should not deter the surgeon from resecting the lesion.

Sarcomatous lesions of the esophagus can be divided into epidermoid carcinomas with spindle cell features, such as carcinosarcoma, and true sarcomas that arise from mesenchymal tissue, such as leiomyosarcoma, fibrosarcoma, and rhabdomyosarcoma. Based on current histologic criteria for diagnosis, fibrosarcoma and rhabdomyosarcoma of the esophagus are extremely rare lesions.

Surgical resection of polypoid sarcoma of the esophagus is the treatment of choice, because radiation therapy has little success and the tumors remain superficial, with local invasion or distant metastases occurring late in the course of the disease. As with carcinoma, the absence of both wall penetration and LN metastases is necessary for curative treatment, and surgical resection is consequently responsible for the majority of the
**Figure 25-71.** A. Computed tomographic scan of a leiomyosarcoma (*black arrow*) that caused compression of the heart and symptoms of syncope. B. Surgical specimen of leiomyosarcoma shown in A with a pedunculated luminal lesion (*white arrow*) and a large extraesophageal component (*black arrow*). There was no evidence of lymph node metastasis at the time of operation.

**Figure 25-72.** A. Barium swallow showing a large polypoid intraluminal esophageal mass causing partial obstruction and dilation of the proximal esophagus. B. Operative specimen showing 9-cm polypoid leiomyoblastoma.
reported 5-year survivals. Resection also provides an excellent means of palliating the patient’s symptoms. The surgical technique for resection and the subsequent restoration of the GI continuity is similar to that described for carcinoma.

In these authors’ experience, four of the eight patients with carcinosarcoma survived for 5 years or longer. Even though this number is small, it suggests that resection produces better results in epithelial carcinoma with spindle cell features than in squamous cell carcinoma of the esophagus. Similarly, with leiomyosarcoma of the esophagus, the same scattered reports exist with little information on survival. Of seven patients with leiomyosarcoma, two died from their disease—one in 3 months and the other 4 years and 7 months after resection. The other five patients were reported to have survived more than 5 years.

It is difficult to evaluate the benefits of resection for leiomyoblastoma of the esophagus, due to the small number of reported patients with tumors in this location. Most leiomyoblastomas occur in the stomach, and 38% of these patients succumb to the cancer in 3 years. Fifty-five percent of patients with extragastric leiomyoblastoma also die from the disease, within an average of 3 years. Consequently, leiomyoblastoma should be considered a malignant lesion and apt to behave like a leiomyosarcoma. The presence of nuclear hyperchromatism, increased mitotic figures (more than one per high-power field), tumor size larger than 10 cm, and clinical symptoms of longer than 6 months’ duration are associated with a poor prognosis.

**BENIGN TUMORS AND CYSTS**

Benign tumors and cysts of the esophagus are relatively uncommon. From the perspectives of both the clinician and the pathologist, benign tumors may be divided into those that are within the muscular wall and those that are within the lumen of the esophagus.

Intramural lesions are either solid tumors or cysts, and the vast majority are leiomyomas. They are made up of varying portions of smooth muscle and fibrous tissue. Fibromas, myomas, fibromyomas, and lipomyomas are closely related and occur rarely. Other histologic types of solid intramural tumors have been described, such as lipomas, neurofibromas, hemangiomas, osteochondromas, granular cell myoblastomas, and glomus tumors, but they are medical curiosities.

Intraluminal lesions are polyoid or pedunculated growths that usually originate in the submucosa, develop mainly into the lumen, and are covered with normal stratified squamous epithelium. The majority of these tumors are composed of fibrous tissue of varying degrees of compactness with a rich vascular supply. Some are loose and myxoid (e.g., myxoma and myxofibroma), some are more collagenous (e.g., fibroma), and some contain adipose tissue (e.g., fibrolipoma). These different types of tumor are frequently collectively designated fibrovascular polyps, or simply as polyps. Pedunculated intraluminal tumors should be removed. If the lesion is not too large, endoscopic removal with a snare is feasible.

**Leiomyoma**

Leiomyomas constitute more than 50% of benign esophageal tumors. The average age at presentation is 38, which is in sharp contrast to that seen with esophageal carcinoma. Leiomyomas are twice as common in males. Because they originate in smooth muscle, 90% are located in the lower two thirds of the esophagus. They are usually solitary, but multiple tumors have been found on occasion. They vary greatly in size and shape. Actually tumors as small as 1 cm in diameter and as large as 10 lb have been removed.

Typically, leiomyomas are oval. During their growth, they remain intramural, having the bulk of their mass protruding toward the outer wall of the esophagus. The overlying mucosa is freely movable and normal in appearance. Dysphagia and pain are the most common complaints, the two symptoms occurring more frequently together than separately. Bleeding directly related to the tumor is rare, and when hematemesis or melena occurs in a patient with an esophageal leiomyoma, other causes should be investigated.

A barium swallow is the most useful method to demonstrate a leiomyoma of the esophagus (Fig. 25-73). In profile, the tumor appears as a smooth, semilunar, or crescent-shaped filling defect that moves with swallowing, is sharply demarcated, and is covered and surrounded by normal mucosa. Esophagoscopy should be performed to exclude the reported observation of a coexistence with carcinoma. The freely movable mass, which bulges into the lumen, should not be biopsied because of an increased chance of mucosal perforation at the time of surgical enucleation. Endoscopic ultrasound is also a useful adjunct in the workup of leiomyoma and provides detail related to the anatomic extent and relationship to surrounding structures.

Despite their slow growth and limited potential for malignant degeneration, leiomyomas should be removed unless there are specific contraindications. The majority can be removed by simple enucleation. If, during removal, the mucosa is inadvertently entered, the defect can be repaired primarily. After tumor removal, the outer esophageal wall should be reconstructed by closure of the muscle layer. The location of the lesion and the extent of surgery required will dictate the approach. Lesions of the proximal and middle esophagus require a right thoracotomy, whereas distal esophageal lesions require a left thoracotomy. Videothoracoscopic and laparoscopic approaches are now frequently used. The mortality rate associated with enucleation is low, and success in relieving the dysphagia is near 100%.
Large lesions or those involving the GEJ may require esophageal resection.

**Esophageal Cyst**

Cysts may be congenital or acquired. Congenital cysts are lined wholly or partly by columnar ciliated epithelium of the respiratory type, by glandular epithelium of the gastric type, by squamous epithelium, or by transitional epithelium. In some, epithelial lining cells may be absent. Confusion over the embryologic origin of congenital cysts has led to a variety of names, such as enteric, bronchogenic, duplication, and mediastinal cysts. Acquired retention cysts also occur, probably as a result of obstruction of the excretory ducts of the esophageal glands.

Enteric and bronchogenic cysts are the most common, and arise as a result of developmental abnormalities during the formation and differentiation of the lower respiratory tract, esophagus, and stomach from the foregut. During its embryologic development, the esophagus is lined successively with simple columnar, pseudostratified ciliated columnar, and, finally, stratified squamous epithelium. This sequence probably accounts for the fact that the lining epithelium may be any or a combination of these; the presence of cilia does not necessarily indicate a respiratory origin.

Cysts vary in size from small to very large, and are usually located intramurally in the middle- to lower-third of the esophagus. Their symptoms are similar to those of a leiomyoma. The diagnosis similarly depends on radiographic, endoscopic, and endosonographic findings. Surgical excision by enucleation is the preferred treatment. During removal, a fistulous tract connecting the cysts to the airways should be sought, particularly in patients who have had repetitive bronchopulmonary infections.

**ESOPHAGEAL PERFORATION**

Perforation of the esophagus constitutes a true emergency. It most commonly occurs following diagnostic or therapeutic procedures. Spontaneous perforation, referred to as Boerhaave’s syndrome, accounts for only 15% of cases of esophageal perforation, foreign bodies for 14%, and trauma for 10%. Pain is a striking and consistent symptom and strongly suggests that an esophageal rupture has occurred, particularly if located in the cervical area following instrumentation of the esophagus, or subcutaneously in a patient with a history of resisting vomiting. If subcutaneous emphysema is present, the diagnosis is almost certain.

Spontaneous rupture of the esophagus is associated with a high mortality rate because of the delay in recognition and treatment. Although there usually is a history of resisting vomiting, in a small number of patients, the injury occurs silently, without any antecedent history. When the chest radiogram of a patient with an esophageal perforation shows air or an effusion in the pleural space, the condition is often misdiagnosed as a pneumothorax or pancreatitis. An elevated pleural amylase caused by the extrusion of saliva through the perforation may fix the diagnosis of pancreatitis in the mind of an unwary physician. If the chest radiogram is normal, a mistaken diagnosis of myocardial infarction or dissecting aneurysm is often made.

Spontaneous rupture usually occurs into the left pleural cavity or just above the GEJ. About 50% of patients have concomitant GERD, suggesting that minimal resistance to the transmission of abdominal pressure into the thoracic esophagus is a factor in the pathophysiology of the lesion. During vomiting, high peaks of intragastric pressure can be recorded, frequently exceeding 200 mmHg, but because extragastric pressure remains almost equal to intragastric pressure, stretching of the gastric wall is minimal. The amount of pressure transmitted to the esophagus varies considerably, depending on the position of the GEJ. When it is in the abdomen and exposed to intra-abdominal pressure, the pressure transmitted to the esophagus is much less than when it is exposed to the negative thoracic pressure. In the latter situation, the pressure in the lower esophagus will frequently equal intragastric pressure if the glottis remains closed. Cadaver studies have shown that when this pressure exceeds 150 mmHg, rupture of the esophagus is apt to occur. When a hiatal hernia is present and the sphincter remains exposed to abdominal pressure, the lesion produced is usually a Mallory-Weiss mucosal tear, and bleeding rather than perforation is the problem. This is due to the stretching of the supra-diaphragmatic portion of the gastric wall. In this situation, the hernia sac represents an extension of the abdominal cavity, and the GEJ remains exposed to abdominal pressure.

**Diagnosis**

Abnormalities on the chest radiogram can be variable and should not be depended upon to make the diagnosis. This is because the abnormalities are dependent on three factors: (a) the time interval between the perforation and the radiographic examination, (b) the site of perforation, and (c) the integrity of the mediastinal pleura. Mediastinal emphysema, a strong indicator of perforation, takes at least 1 hour to be demonstrated, and is present in only 40% of patients. Mediastinal widening secondary to edema may not occur for several hours. The site of perforation also can influence the radiographic findings. In cervical perforation, cervical emphysema is common and mediastinal emphysema rare; the converse is true for thoracic perforations. Frequently, air will be visible in the erector spinae muscles on a neck radiogram before it can be palpated or seen on a chest radiogram (Fig. 25-74). The integrity of the mediastinal pleura influences the radiographic abnormality in that rupture of the pleura results in a pneumothorax, a finding that is seen in 77% of patients. In two thirds of patients, the perforation is on the left side; in one fifth, it is on the right side; and in one tenth, it is bilateral. If pleural integrity is maintained, mediastinal emphysema (rather than a pneumothorax) appears rapidly. A pleural effusion secondary to inflammation of the mediastinum occurs late. In 9% of patients, the chest radiogram is normal.

The diagnosis is confirmed with a contrast esophagram, which will demonstrate extravasation in 90% of patients. The use of a water-soluble medium such as Gastrografin is preferred. Of concern is that there is a 10% false-negative rate. This may be due to obtaining the radiographic study with the patient in the upright position. When the patient is upright, the passage of water-soluble contrast material can be too rapid to demonstrate a small perforation. The studies should be done with the patient in the right lateral decubitus position (Fig. 25-75). In this, the contrast material fills the entire length of the esophagus, allowing the actual site of perforation and its interconnecting cavities to be visualized in almost all patients.

**Management**

The key to optimum management is early diagnosis. The most favorable outcome is obtained following primary closure of the perforation within 24 hours, resulting in 80% to 90% survival. Figure 25-76 is an operative photograph taken through a left
thoracotomy of an esophageal rupture following a pneumatic dilation for achalasia. The most common location for the injury is the left lateral wall of the esophagus, just above the GEJ. To get adequate exposure of the injury, a dissection similar to that described for esophageal myotomy is performed. A flap of stomach is pulled up and the soiled fat pad at the GEJ is removed. The edges of the injury are trimmed and closed primarily (Fig. 25-77). The closure is reinforced with the use of a pleural patch or construction of a Nissen fundoplication.

Mortality associated with immediate closure varies between 8% and 20%. After 24 hours, survival decreases to <50%, and is not influenced by the type of operative therapy (i.e., drainage alone or drainage plus closure of the perforation). If the time delay before closing a perforation approaches 24 hours and the tissues are inflamed, division of the cardia and resection of the diseased portion of the esophagus are recommended. The remainder of the esophagus is mobilized, and as much normal esophagus as possible is saved and brought out as an end cervical esophagostomy. In some situations, the retained esophagus may be so long that it loops down into the chest. The contaminated mediastinum is drained and a feeding jejunostomy tube is inserted. The recovery from sepsis is often immediate, dramatic, and reflected by a marked improvement in the patient’s condition over a 24-hour period. On recovery from the sepsis, the patient is discharged and returns on a subsequent date for reconstruction with a substernal colon interposition. Failure to apply this aggressive therapy can result in a mortality rate in excess of 50% in patients in whom the diagnosis has been delayed.

Nonoperative management of esophageal perforation has been advocated in select situations. The choice of conservative therapy requires skillful judgment and necessitates careful radiographic examination of the esophagus. This course of management usually follows an injury occurring during dilation of esophageal strictures or pneumatic dilations of achalasia. Conservative management should not be used in patients who have free perforations into the pleural space. Cameron proposed three criteria for the nonoperative management of esophageal perforation: (a) the esopagram must show the perforation to be contained within the mediastinum and drain well back into the esophagus (Fig. 25-78), (b) symptoms should be mild, and (c) there should be minimal evidence of clinical sepsis. If these conditions are met, it is reasonable to treat the patient with

Figure 25-74. Chest radiogram showing air in the deep muscles of the neck following perforation of the esophagus (arrow). This is often the earliest sign of perforation and can be present without evidence of air in the mediastinum.

Figure 25-75. Radiographic study of a patient with a perforation of the esophagus using water-soluble contrast material. The patient is placed in the lateral decubitus position with the left side up to allow complete filling of the esophagus and demonstration of the defect.

Figure 25-76. Left thoracotomy in a patient with an esophageal rupture at the gastroesophageal junction following forceful dilation of the lower esophagus for achalasia (the surgical clamp is on the stomach, and the Penrose drain encircles the esophagus). The injury consists of a mucosal perforation and extensive splitting of the esophageal muscle from just below the Penrose drain to the stomach.
hyperalimentation, antibiotics, and cimetidine to decrease acid secretion and diminish pepsin activity. Oral intake is resumed in 7 to 14 days, dependent on subsequent radiographic examinations.

MALLORY-WEISS SYNDROME

In 1929, Mallory and Weiss described four patients with acute upper GI bleeding who were found at autopsy to have mucosal tears at the GEJ. This syndrome, characterized by acute upper GI bleeding following vomiting, is considered to be the cause of up to 15% of all severe upper GI bleeds. The mechanism is similar to spontaneous esophageal perforation: an acute increase in intra-abdominal pressure against a closed glottis in a patient with a hiatal hernia.

Mallory-Weiss tears are characterized by arterial bleeding, which may be massive. Vomiting is not an obligatory factor, as there may be other causes of an acute increase in intra-abdominal pressure, such as paroxysmal coughing, seizures, and retching. The diagnosis requires a high index of suspicion, particularly in the patient who develops upper GI bleeding following prolonged vomiting or retching.

CAUSTIC INJURY

Accidental caustic lesions occur mainly in children, and, in general, rather small quantities of caustics are taken. In adults or teenagers, the swallowing of caustic liquids is usually deliberate, during a suicide attempt, and greater quantities are swallowed. Alkalis are more frequently swallowed accidentally than acids, because strong acids cause an immediate burning pain in the mouth.

Pathology

The swallowing of caustic substances causes an acute and a chronic injury. During the acute phase, care focuses on controlling the immediate tissue injury and the potential for perforation. During the chronic phase, the focus is on treatment
of strictures and disturbances in pharyngeal swallowing. In the acute phase, the degree and extent of the lesion are dependent on several factors: the nature of the caustic substance, its concentration, the quantity swallowed, and the time the substance is in contact with the tissues.

Acids and alkalis affect tissue in different ways. Alkalis dissolve tissue, and therefore penetrate more deeply, while acids cause a coagulative necrosis that limits their penetration. Animal experiments have shown that there is a correlation between the depth of the lesion and the concentration of sodium hydroxide solution. When a solution of 3.8% comes into contact with the esophagus for 10 seconds, it causes necrosis of the mucosa and the submucosa, but spares the muscular layer. A concentration of 22.5% penetrates the whole esophageal wall and into the periesophageal tissues. Cleansing products can contain up to 90% sodium hydroxide. The strength of esophageal contractions varies according to the level of the esophagus, being weakest at the striated muscle–smooth muscle interface. Consequently, clearance from this area may be somewhat slower, allowing caustic substances to remain in contact with the mucosa longer. This explains why the esophagus is preferentially and more severely affected at this level than in the lower portions.

The lesions caused by lye injury occur in three phases. First is the acute necrotic phase, lasting 1 to 4 days after injury. During this period, coagulation of intracellular proteins results in cell necrosis, and the living tissue surrounding the area of necrosis develops an intense inflammatory reaction. Second is the ulceration and granulation phase, starting 3 to 5 days after injury. During this period, the superficial necrotic tissue sloughs, leaving an ulcerated, acutely inflamed base, and granulation tissue fills the defect left by the sloughed mucosa. This phase lasts 10 to 12 days, and it is during this period that the esophagus is the weakest. Third is the phase of cicatrization and scar, which begins the third week following injury. During this period, the previously formed connective tissue begins to contract, resulting in narrowing of the esophagus. Adhesions between granulating areas occur, resulting in pockets and bands. It is during this period that efforts must be made to reduce stricture formation.

**Clinical Manifestations**

The clinical picture of an esophageal burn is determined by the degree and extent of the lesion. In the initial phase, complaints consist of pain in the mouth and substernal region, hypersalivation, pain on swallowing, and dysphagia. The presence of fever is strongly correlated with the presence of an esophageal lesion. Bleeding can occur, and frequently, the patient vomits. These initial complaints disappear during the quiescent period of ulceration and granulation. During the cicatrization and scar phase, the complaint of dysphagia reappears and is due to fibrosis and retraction, resulting in narrowing of the esophagus. Of the patients who develop strictures, 60% do so within 1 month, and 80% within 2 months. If dysphagia does not develop within 8 months, it is unlikely that a stricture will occur. Serious systemic reactions such as hypovolemia and acidosis resulting in renal damage can occur in cases in which the burns have been caused by strong acids. Respiratory complications such as laryngospasm, laryngoelema, and occasionally pulmonary edema can occur, especially when strong acids are aspirated.

Inspection of the oral cavity and pharynx can indicate that caustic substances were swallowed, but does not reveal that the esophagus has been burned. Conversely, esophageal burns can be present without apparent oral injuries. Because of this poor correlation, early esophagoscopy is advocated to establish the presence of an esophageal injury. To lessen the chance of perforation, the scope should not be introduced beyond the proximal esophageal lesion. The degree of injury can be graded according to the criteria listed in Table 25-16. Even if the esophagoscopy is normal, strictures may appear later. Radiographic examination is not a reliable means to identify the presence of early esophageal injury, but is important in later follow-up to identify strictures. The most common locations of caustic injuries are shown in Table 25-17.

**Treatment**

Treatment of a caustic lesion of the esophagus is directed toward management of both the immediate and late consequences of the injury. The immediate treatment consists of limiting the burn by administering neutralizing agents. To be effective, this must be done within the first hour. Lye or other alkali can be neutralized with half-strength vinegar, lemon juice, or orange juice. Acid can be neutralized with milk, egg white, or antacids. Sodium bicarbonate is not used because it generates carbon dioxide, which might increase the danger of perforation. Emetics are contraindicated, because vomiting renews the contact of the caustic substance with the esophagus and can contribute to perforation if too forceful. Hypovolemia is corrected and broad-spectrum antibiotics are administered to lessen the inflammatory reaction and prevent infectious complications. If necessary, a feeding jejunostomy tube is inserted to provide nutrition. Oral feeding can be started when the dysphagia of the initial phase has regressed.

In the past, surgeons waited until the appearance of a stricture before starting treatment. Currently, dilations are started the first day after the injury, with the aim of preserving the esophageal lumen by removing the adhesions that occurred in the injured segments. However, this approach is controversial in that dilations can traumatize the esophagus, causing bleeding, and perforation, and there are data indicating that excessive dilations cause increased fibrosis secondary to the added trauma. The use of steroids to limit fibrosis has been shown to be effective in animals, but their effectiveness in human beings has not been established.

Extensive necrosis of the esophagus frequently leads to perforation, and is best managed by resection. When there is extensive gastric involvement, the esophagus is nearly always necrotic or severely burned, and total gastrectomy and near-total esophagectomy are necessary. The presence of air in the esophageal wall is a sign of muscle necrosis and impending perforation and is a strong indication for esophagectomy.

Management of acute injury is summarized in the algorithm in Fig. 25-79. Some authors have advocated the use of an intraluminal esophageal stent (Fig. 25-80) in patients who are operated on and found to have no evidence of extensive esophagogastric necrosis. In these patients, a biopsy of the posterior gastric wall should be performed to exclude occult injury. If, histologically, there is a question of viability, a second-look operation should be done within 36 hours. If a stent is inserted, it should be kept in position for 21 days, and removed after a satisfactory barium esophagogram. Esophagoscopy should be done, and, if strictures are present, dilations initiated.

Once the acute phase has passed, attention is turned to the prevention and management of strictures. Both antegrade dilation with a Hurst or Maloney bougie and retrograde dilation with a Tucker bougie have been satisfactory. In a series of 1079 patients, early dilations started during the acute phase gave excellent results in 78%, good results in 13%, and poor results in 2%. During the treatment 55 patients died. In contrast, of 333 patients whose strictures were dilated when they became symptomatic, only 21% had excellent results, 46% good, and 6% poor, with three dying during the process. The length of time the surgeon should persist with dilation before consideration of esophageal resection is problematic. An adequate lumen should be re-established within 6 months to 1 year, with progressively longer intervals between dilations. If, during the course of treatment, an adequate lumen cannot be established or maintained (i.e., smaller bougies must be used), operative intervention should be considered. Surgical intervention is indicated when there is (a) complete stenosis in which all attempts from above and below have failed to establish a lumen, (b) marked irregularity and pocketing on barium swallow, (c) the development of a severe periesophageal reaction or mediastinitis with dilation, (d) a fistula, (e) the inability to dilate or maintain the lumen above a 40F bougie, or (f) a patient who is unwilling or unable to undergo prolonged periods of dilation.

The variety of abnormalities seen requires that creativity be used when considering esophageal reconstruction.
ESOPHAGUS AND DIAPHRAGMATIC HERNIA

Esophagoplasties are now used much less frequently than they were in the past, and are mainly of historical interest. Currently, the stomach, jejunum, and colon are the organs used to replace the esophagus, through either the posterior mediastinum or the retrosternal route. A retrosternal route is chosen when there has been a previous esophagectomy or there is extensive fibrosis in the posterior mediastinum. When all factors are considered, the order of preference for an esophageal substitute is (a) colon, (b) stomach, and (c) jejunum. Free jejunal grafts based on the superior thyroid artery have provided excellent results. Whatever method is selected, it must be emphasized that these procedures cannot be taken lightly; minor errors of judgment or technique may lead to serious or even fatal complications.

Critical in the planning of the operation is the selection of cervical esophagus, pyriform sinus, or posterior pharynx as the site for proximal anastomosis. The site of the upper anastomosis depends on the extent of the pharyngeal and cervical esophageal damage encountered. When the cervical esophagus is destroyed and a pyriform sinus remains open the anastomosis can be made to the hypopharynx (Fig. 25-81). When the pyriform sinuses are completely stenosed, a transglottic approach is used to perform an anastomosis to the posterior oropharyngeal wall (Fig. 25-82). This allows excision of supraglottic strictures and elevation and anterior tilting of the larynx. In both of these situations, the patient must relearn to swallow. Recovery is long and difficult and may require several endoscopic dilations, and often reoperations. Sleeve resections of short strictures are not successful because the extent of damage to the wall of the esophagus can be greater than realized, and almost invariably the anastomosis is carried out in a diseased area.

The management of a bypassed damaged esophagus after injury is problematic. If the esophagus is left in place, ulceration from gastroesophageal reflux or the development of carcinoma must be considered. The extensive dissection necessary to remove the esophagus, particularly in the presence of marked periesophagitis, is associated with significant morbidity. Leaving the esophagus in place preserves the function of the vagus nerves, and, in turn, the function of the stomach. On the other hand, leaving a damaged esophagus in place can result in multiple blind sacs and subsequent development of mediastinal abscesses years later. Most experienced surgeons recommend that the esophagus be removed unless the operative risk is unduly high.

ACQUIRED FISTULA

The esophagus lies in close contact with the membranous portion of the trachea and left bronchus, predisposing to the formation of fistula to these structures. Most acquired esophageal fistulas are to the tracheobronchial tree, and secondary to either esophageal or pulmonary malignancy. Traumatic fistulas and those associated with esophageal diverticula account for the remainder. Fistulas associated with traction diverticula are usually due to mediastinal inflammatory disease, and traumatic fistulas usually occur secondary to penetrating wounds, lye ingestion, or iatrogenic injury.

These fistulas are characterized by paroxysmal coughing following the ingestion of liquids, and by recurrent or chronic pulmonary infections. The onset of cough immediately after swallowing suggests aspiration, whereas a brief delay (30–60 seconds) suggests a fistula.

Spontaneous closure is rare, owing to the presence of malignancy or a recurrent infectious process. Surgical treatment of benign fistulas consists of division of the fistulous tract, resection of irreversibly damaged lung tissue, and closure of the esophageal defect. To prevent recurrence, a pleural flap should be interposed. Treatment of malignant fistulas is difficult, particularly in the presence of prior irradiation. Generally, only palliative treatment is indicated. This can best be done by using a
specially designed esophageal endoprosthesis that bridges and occludes the fistula, allowing the patient to eat. A salivary tube is also a good option for proximal esophageal fistulas. This tube has a proximal “lip” that rests on the cricopharyngeal muscle and thereby directs the saliva into the tube and past the fistula. Rarely, esophageal diversion, coupled with placement of a feeding jejunostomy, can be used as a last resort.

**TECHNIQUES OF ESOPHAGEAL RECONSTRUCTION**

Options for esophageal substitution include gastric advancement, colonic interposition, and either jejunal free transfer or advancement into the chest. Rarely, combinations of these grafts will be the only possible option. The indications for esophageal resection and substitution include malignant and end-stage benign disease. The latter includes reflux- or drug-induced stricture formation that cannot be dilated without damage to the esophagus, a dilated and tortuous esophagus secondary to severe motility disorders, lye-induced strictures, and multiple previous antireflux procedures. The choice of esophageal substitution has significant impact upon the technical difficulty of the procedure, and influences the long-term outcome.

**Partial Esophageal Resection**

Distal benign lesions, with preserved proximal esophageal function, are best treated with the interposition of a segment of proximal jejunum into the chest and primary anastomosis. A jejunal interposition can reach to the inferior border of the pulmonary hila with ease, but the architecture of its blood supply rarely allows the use of the jejunum proximal to this point. Because the anastomosis is within the chest, a thoracotomy is necessary. The jejunum is a dynamic graft and contributes to bolus transport, whereas the stomach and colon function more as a conduit. The stomach is a poor choice in this circumstance because of the propensity for the reflux of gastric contents into the proximal remaining esophagus following an intrathoracic esophagogastrotomy. It is now well recognized that this occurs, and can lead to incapacitating symptoms and esophageal destruction in some patients. Short segments of colon, on the other hand, lack significant motility and have a propensity for the development of esophagitis proximal to the anastomosis.

Replacement of the cervical portion of the esophagus, while preserving the distal portion, is occasionally indicated in cervical esophageal or head and neck malignancy, and following the ingestion of lye. Free transfer of a portion of jejunum to the neck has become a viable option and is successful in the majority of cases. Revascularization is achieved via use of the internal mammary artery and the internal mammary or innominate vein. Removal of the sternoclavicular joint aids in performing the vascular and distal esophageal anastomosis (Fig. 25-83).

**Reconstruction after Total Esophagectomy**

Neither the intrathoracic stomach nor the intrathoracic colon functions as well as the native esophagus after an esophagogastrectomy. The choice between these organs will be influenced by several factors, such as the adequacy of their blood supply and the length of resected esophagus that they are capable of bridging. If the stomach shows evidence of disease, or has been contracted or reduced by previous gastric surgery, the length available for esophageal replacement may not be adequate. The presence of diverticular disease, unrecognized carcinoma, or colitis prohibits the use of the colon. The blood supply of the colon is more affected by vascular disease than the blood supply of the stomach, which may prevent its use. Of the two, the colon provides the longest graft. The stomach can usually reach to the neck if the amount of lesser curvature resected does not interfere with the blood supply to the fundus. Gastric interposition has the advantage that only one anastomosis is required. On the other hand, there is greater potential for aspiration of gastric juice or stricture of the cervical anastomosis from chronic reflux when stomach is used for replacement.

---

Following an esophagogastrectomy, patients may have discomfort during or shortly after eating. The most common symptom is a postprandial pressure sensation or a feeling of being full, which probably results from the loss of the gastric reservoir. This symptom is less common when the colon is used as an esophageal substitute, probably because the distal third of the stomach is retained in the abdomen and the interposed colon provides an additional reservoir function.

King and Hölscher have reported a 40% and 50% incidence of dysphagia after re-establishing GI continuity with the stomach following esophagogastrectomy. This incidence is similar to Orringer’s results after using the stomach to replace the esophagus in patients with benign disease. More than one-half of the patients experienced dysphagia postoperatively; two-thirds of this group required postoperative dilation and one-fourth had persistent dysphagia and required home dilation. In contrast, dysphagia is uncommon and the need for dilation is rare following a colonic interposition. Isolaüri reported on 248 patients with colonic interpositions and noted a 24% incidence of dysphagia 12 months after the operation. When it occurred, the most common cause was recurrent mediastinal tumor. The high incidence of dysphagia with the use of the stomach is probably related to the esophagogastric anastomosis in the neck and the resulting difficulty of passing a swallowed bolus.

Another consequence of the transposition of the stomach into the chest is the development of postoperative duodenogastric reflux, probably due to pyloric denervation, and adding a pyloroplasty may worsen this problem. Following gastric advancement, the pylorus lies at the level of the esophageal hiatus, and a distinct pressure differential develops between the intrathoracic gastric and intra-abdominal duodenal lumina. Unless the pyloric valve is extremely efficient, the pressure differential will encourage reflux of duodenal contents into the stomach. Duodenogastric reflux is less likely to occur following colonic interposition, because there is sufficient intra-abdominal colon to be compressed by the abdominal pressure, and the pylorus and duodenum remain in their normal intra-abdominal position.

Although there is general acceptance of the concept that an esophagogastric anastomosis in the neck results in less postoperative esophagitis and stricture than one at a lower level, reflux esophagitis following a cervical anastomosis does occur, albeit at a lower rate than when the anastomosis is at a lower level. Most patients undergo cervical esophagostomy for malignancy; thus the long-term sequelae of an esophagogastric anastomosis in the neck are not of concern. However, patients who have had a cervical esophagogastrostomy for benign disease may develop problems associated with the anastomosis in the fourth or fifth postoperative year that are severe enough to require anastomatic revision. This is less likely in patients who have had a colonic interposition for esophageal replacement. Consequently, in patients who have a benign process or a potentially curable carcinoma of the esophagus or cardia, a colonic interposition is used to obviate the late problems associated with a cervical esophagogastric stomastomy. Colonic interposition for esophageal substitution is a more complex procedure than gastric advancement, with the potential for greater perioperative morbidity, particularly in inexperienced hands.

**Composite Reconstruction**

Occasionally, a combination of colon, jejunum, and stomach is the only reconstructive option available. This situation may arise when there has been previous gastric or colonic resection, when dysphagia has recurred after a previous esophageal resection, or following postoperative complications such as ischemia of an esophageal substitute. Although not ideal, combinations of colon, jejunum, and stomach used to restore GI continuity function surprisingly well, and allow alimentary reconstruction in an otherwise impossible situation.

**Vagal Sparing Esophagostomy with Colon Interposition**

Traditional esophagectomy typically results in bilateral vagotomy and its attendant consequences. It is likely that symptoms such as dumping, diarrhea, early satiety, and weight loss seen in 15% to 20% of patients postesophagostomy are at least in part, if not completely, due to vagal interruption. The technique of vagal sparing esophagectomy with colon interposition has been described in an effort to avoid the morbidities associated with standard esophagectomy.

Through an upper midline abdominal incision, the right and left vagal nerves are identified, circled with a tape, and retracted to the right. A limited, highly selective proximal gastric vagotomy is performed along the cephalad 4 cm of the lesser curvature. The stomach is divided with an Endo-GIA stapler just below the GEJ. The colon is prepared to provide an interposed segment as previously described. A neck incision is made along the anterior border of the left sternocleidomastoid muscle, and the strap muscles are exposed. The omohyoid muscle is divided at its pulley, and the sternohyoideus and sternothyroid muscles are divided at their manubrial insertion. The left carotid sheath is retracted laterally and the thyroid and trachea medially. The left inferior thyroid artery is ligated laterally as it passes under the left common carotid artery. The left recurrent laryngeal nerve is identified and protected. The esophagus is dissected circumferentially in an inferior direction, from the neck to the apex of the right chest, to avoid injury to the right recurrent laryngeal nerve. The esophagus is divided at the level of the thoracic inlet, leaving about 3 to 4 cm of cervical esophagus. The proximal esophagus is retracted anteriorly and to the right with the use of two sutures to keep saliva and oral contents from contaminating the neck wound.

Returning to the abdomen, the proximal staple line of the gastric division is opened and the esophagus is flushed with povidone-iodine solution. A vein stripper is passed up the esophagus into the neck wound. The distal portion of the esophagus in the neck is secured tightly around the stripping cable with “endoloops” and an umbilical tape for a trailer. The tip of the stripper is exchanged for a mushroom head, and the stripper is pulled back into the abdomen, inverting the esophagus as it transverses the posterior mediastinum. This maneuver strips the branches of the esophageal plexus off the longitudinal muscle of the esophagus, preserving the esophageal plexus along with the proximal vagal nerves and the distal vagal nerve trunks. In patients with end-stage achalasia, only the mucosa is secured around the stripping cable, so that it alone is stripped and the dilated muscular wall of the esophagus, with its enriched blood supply, remains. The resulting mediastinal tunnel, or in the case of achalasia the muscular tube, is dilated with a Foley catheter containing 90 mL of fluid in the balloon. The previously prepared interposed portion of the transverse colon is passed behind the stomach and up through the mediastinal tunnel into the neck. An end-to-end anastomosis is performed to the cervical esophagus using a single layer technique. The colon is pulled taut and secured to the left crus with four or
five interrupted sutures. Five centimeters below the crura, an opening is made in the mesentry adjacent to the colon along its mesenteric border, through which an Endo-GIA stapler is passed and the colon is divided. The proximal end, which is the distal end of the interposed colon, is anastomosed high on the posterior fundic wall of the stomach, using a triangular stapling anastomotic technique. This is done by stapling longitudinally the stomach and colon together with a 75-mm Endo-GIA stapler, spreading the base of the incision apart, and closing it with a T-55 stapler. Colonic continuity is re-established by bringing the proximal right colon to the distal staple line in the left colon and performing an end-to-end anastomosis using a double layer technique.

Although conceptually appealing, preservation of vagal nerve integrity or the gastric reservoir function after vagal sparing esophagectomy only recently has been validated. Banki and associates compared patients undergoing vagal sparing esophagectomy to those with conventional esophagectomy and colon or gastric interposition. This study showed that vagal sparing esophagectomy preserved gastric secretion, gastric emptying, meal capacity, and body mass index, compared to esophagogastro-intestomy with colon interposition or standard esophagectomy with gastric pull-up. Vagal sparing esophagectomy patients functioned, for the most part, similarly to normal subjects, allowing them to eat a normal meal, free of dumping or diarrhea. These results indicate that the vagal sparing esophagectomy procedure does indeed preserve the vagal nerves, and may be considered in the treatment of benign and early malignant lesions requiring esophagectomy.

The stomach is a remarkable organ with important digestive, nutritional, and endocrine functions. The stomach stores and facilitates the digestion and absorption of ingested food, and it helps regulate appetite. Treatable diseases of the stomach are common, and it is accessible and relatively forgiving. Thus, the stomach is a favorite therapeutic target. To provide intelligent diagnosis and treatment, the physician and surgeon must understand gastric anatomy, physiology, and pathophysiology. This includes a sound understanding of the mechanical, secretory, and endocrine processes through which the stomach accomplishes its important functions; and a familiarity with the common benign and malignant gastric disorders of clinical significance. The surgeon must also understand the indications, complications, and outcomes of procedures utilized to treat diseases of the stomach. The purpose of this chapter is to enhance the reader’s current understanding and familiarity with these concepts and topics. Some important milestones in the history of gastric surgery are listed in Table 26-1.

**ANATOMY**

**Anatomic Relationships and Gross Morphology**

The stomach is readily recognizable as the asymmetrical, pear-shaped, most proximal abdominal organ of the digestive tract (Fig. 26-1). The part of the stomach attached to the esophagus is called the cardia. Just proximal to the cardia at the gastroesophageal (GE) junction is the anatomically indistinct but physiologically demonstrable lower esophageal sphincter. At the distal end, the readily apparent pyloric sphincter connects the stomach to the proximal duodenum. The stomach is relatively fixed at these points, but the large midportion is quite mobile with the shorter lesser curvature on the right and the longer greater curvature on the left. The superior-most part of the stomach is the distensible fundus, bounded superiorly by the diaphragm and laterally by the spleen. The angle of His is where the fundus meets the left side of the GE junction. Generally, the inferior extent of the...
Key Points

1. Any patient admitted to a hospital because of peptic ulcer disease should be considered for lifelong acid suppression.
2. Lifelong acid suppressive medication may be equivalent to surgical vagotomy in preventing recurrent peptic ulcer or ulcer complications.
3. Roux-en-Y gastrojejunostomy should be avoided unless more than half of the stomach has been removed. Otherwise marginal ulceration and/or gastric stasis (Roux syndrome) may become problematic.
4. Gastric resection for peptic ulcer should be avoided in the asthenic or high-risk patient, if possible.
5. Many patients with locally advanced gastric cancer (T2b, T3, T4) are cured by an oncologically sound operation that includes wide margins and adequate lymphadenectomy.
6. Most patients with primary gastric lymphoma can be treated without gastric resection.
7. Gastric carcinoids should usually be removed either endoscopically or surgically. The surgeon should treat gastric carcinoid without hypergastrinemia (type III) as if it were malignant.

The stomach is considered to be the horizontal plane of the GE junction, where the body (corpus) of the stomach begins. The body of the stomach contains most of the parietal (oxyntic) cells, some of which are also present in the cardia and fundus. At the angularis, incisura the lesser curvature turns rather abruptly to the right, marking the anatomic beginning of the antrum, which comprises the distal 25% to 30% of the stomach.

The organs that commonly abut the stomach are the liver, colon, spleen, pancreas, and occasionally the kidney (Fig. 26-2). The left lateral segment of the liver usually covers a large part of the anterior stomach. Inferiorly, the stomach is attached to the transverse colon by the gastrocolic omentum. The lesser curvature is tethered to the liver by the hepatogastric ligament, also referred to as the lesser omentum or pars flaccida. Posterior to the stomach is the lesser omental bursa and the pancreas.

**Arterial and Venous Blood Supply**

The stomach is the most richly vascularized portion of the alimentary tube with ample blood flow and a dense intramural vascular anastomotic network. The large majority of the gastric blood supply is from the celiac axis via four named arteries (Fig. 26-3). The left and right gastric arteries form an anastomotic arcade along the lesser curvature, and the right and left gastroepiploic arteries form an arcade along the greater gastric curvature. The consistently largest artery to the stomach is the left gastric artery, which usually arises directly from the celiac trunk and divides into an ascending and descending branch along the lesser gastric curvature. Approximately 20% of the time, the left gastric artery supplies an aberrant vessel that travels in the gastrohepatic ligament (lesser omentum) to the left side of the liver. Rarely, this is the only arterial blood supply to this part of the liver, and inadvertent ligation may lead to clinically significant hepatic ischemia in this unusual circumstance. The more common smaller aberrant left hepatic artery may be ligated without significant consequences.

The second largest artery to the stomach is the right gastroepiploic artery, which arises consistently from the gastroduodenal artery behind the first portion of the duodenum. The left gastroepiploic artery arises from the splenic artery, and, together with the right gastroepiploic artery, forms the rich gastroepiploic arcade along the greater curvature. The right gastric artery usually arises from the hepatic artery near the pylorus and hepatoduodenal ligament, and runs proximally along the distal stomach. In the fundus along the proximal greater curvature, the short gastric arteries and veins arise from the splenic circulation. There also may be additional vascular branches to the proximal stomach from the phrenic and splenic circulation.

The veins draining the stomach generally parallel the arteries. The left gastric (coronary vein) and right gastric veins usually drain into the portal vein, though occasionally the coronary vein drains into the splenic vein. The right gastroepiploic vein drains into the superior mesenteric vein near the inferior border of the pancreatic neck, and the left gastroepiploic vein drains into the splenic vein.

The richness of the gastric blood supply and the extensiveness of the anastomotic connections have some important clinical implications, such as: a) At least two of the four named gastric arteries may be occluded or ligated with impunity. This is
done routinely when the stomach is mobilized and pedicled on the right gastric and right gastroepiploic vessels to reach into the neck as an esophageal replacement (see Chapter 25) or during sleeve gastrectomy for weight loss when the gastroepiploic arcade is interrupted distally and resected (see Chapter 27),
b) Following radical subtotal gastrectomy during which the right and left gastric arteries and both gastroepiploic arteries are all ligated, the gastric remnant is adequately supplied by short gastric arteries as long as the splenic artery is patent and intact;
c) Angiographic control of gastric bleeding from deep ulcer or tumor often requires embolization of more than one feeding artery; d) Because of the rich venous interconnections in the stomach, a distal splenorenal shunt, which connects the distal end of the divided splenic vein to the side of the left renal vein, can effectively decompress esophagogastric varices in patients with portal hypertension.\(^{8,9}\)

### Lymphatic Drainage

Generally speaking, the gastric lymphatics parallel the blood vessels (Fig. 26-4).\(^{10}\) The cardia and medial half of the corpus commonly drain to nodes along the left gastric and celiac axis. The lesser curvature side of the antrum usually drains to the right gastric and pyloric nodes, while the greater curvature half of the distal stomach drains to the nodes along the right gastroepiploic chain. The proximal greater curvature side of the stomach usually drains into nodes along the left gastroepiploic or splenic hilum. The nodes along both the greater and lesser curvature commonly drain into the celiac nodal basin. There is a rich anastomotic network of lymphatics that drain the stomach, often in a somewhat unpredictable fashion. Thus, a tumor arising in the distal stomach may give rise to positive lymph nodes in the splenic hilum. The rich intramural plexus of lymphatics and veins accounts for the fact that there can be microscopic evidence of malignant cells in the gastric wall at a resection margin that is several centimeters away from palpable malignant tumor. It also helps explain the not infrequent finding of positive lymph nodes which may be many centimeters away from the primary tumor, with closer nodes that remain negative.

Extensive and meticulous lymphadenectomy is considered by many surgeons to be an important part of the operation for gastric cancer. Surgeons and pathologists have numbered the primary and secondary lymph node groups to which the stomach drains (see Fig. 26-4).\(^{11,12}\)

### Innervation\(^{13}\)

The vagus nerves provide the extrinsic parasympathetic innervation to the stomach, and acetylcholine is the most important neurotransmitter. From the vagal nucleus in the floor of the fourth cerebral ventricle, the vagus traverses the neck in the carotid sheath and enters the mediastinum, where it gives off the recurrent laryngeal nerve and divides into several branches around the esophagus. These branches come together again above the esophageal hiatus and form the left (anterior) and right (posterior) vagal trunks (mnemonic LARP). Near the GE junction the anterior vagus sends a branch (or branches) to the liver in the gastrohepatic ligament, and continues along the lesser curvature as the anterior nerve of Latarjet (Fig. 26-5). Similarly, the posterior vagus sends branches to the celiac plexus and continues along the posterior lesser curvature. The nerves of Latarjet send segmental branches to the body of the stomach before they terminate near the angularis incisura as the “crow’s foot,” sending branches to the antpyloric region. There may be additional branches to the distal stomach and pylorus that travel near the right gastric and/or gastroepiploic arteries. In 50% of patients, there are more than two vagal nerves at the esophageal hiatus. The branch that the posterior vagus sends to the posterior fundus
is termed the *criminal nerve of Grassi*. This branch typically arises above the esophageal hiatus and is easily missed during truncal or highly selective vagotomy (HSV). Vagal fibers originating in the brain synapse with neurons in Auerbach’s myenteric plexus and Meissner’s submucosal plexus. In the stomach the vagus nerves affect secretion (including acid), motor function, and mucosal bloodflow and cytoprotection. They also play a role in appetite control and perhaps even mucosal immunity and inflammation. Most of the axons contained in the vagal trunks are afferent (i.e., carrying stimuli from the viscera to the brain).

The extrinsic sympathetic nerve supply to the stomach originates at spinal levels T5 through T10 and travels in the splanchnic nerves to the celiac ganglion. Postganglionic sympathetic nerves then travel from the celiac ganglion to the stomach along the blood vessels.

Neurons in the myenteric and submucosal plexuses constitute the intrinsic nervous system of the stomach. There may be more intrinsic gastric neurons than extrinsic neurons, but their function is poorly understood.

It is obviously an oversimplification (and incorrect) to think exclusively of the vagus as the cholinergic system and the sympathetic system as the adrenergic system of innervation. Although acetylcholine is an important neurotransmitter mediating vagal function, and epinephrine is important in the sympathetic nerves, both systems (as well as the intrinsic neurons) have various and diverse neurotransmitters, including cholinergic, adrenergic, and peptidergic (e.g., substance P and somatostatin).

**Histology**

There are four distinct layers of the gastric wall: mucosa, submucosa, muscularis propria, and serosa (Fig. 26–6). The inner layer of the stomach is the mucosa, which is lined with columnar epithelial cells of various types. Beneath the basement membrane of the epithelial cells is the lamina propria, which contains connective tissue, blood vessels, nerve fibers, and inflammatory cells. Beneath the lamina propria is a thin muscle layer called the *muscularis mucosa*, the deep boundary of the mucosal layer of the gut. The epithelium, lamina propria, and muscularis mucosa constitute the mucosa (Fig. 26–7). The epithelium of the gastric mucosa is columnar glandular. A scanning electron micrograph shows a smooth mucosal carpet punctuated by the openings of the gastric glands. The gastric glands are lined with different types of epithelial cells, depending upon their location in the stomach (Fig. 26–8, Table 26–2). There are also endocrine cells present in the gastric glands. Progenitor cells at the base of the glands differentiate and replenish sloughed cells on a regular basis. Throughout the stomach, the carpet consists primarily of mucus-secreting surface epithelial cells (SECs) that
extend down into the gland pits for variable distances. These cells also secrete bicarbonate and play an important role in protecting the stomach from injury due to acid, pepsin, and/or ingested irritants. In fact, all epithelial cells of the stomach (except the endocrine cells) contain carbonic anhydrase and are capable of producing bicarbonate.

In the cardia, the gastric glands are branched and secrete primarily mucus and bicarbonate, but not much acid. In the fundus and body, the glands are more tubular and the pits are deep. Parietal and chief cells are common in these glands (Fig. 26-9). Histamine-secreting enterochromaffin-like (ECL) cells and somatostatin-secreting D cells are also found. Parietal cells secrete acid and intrinsic factor into the gastric lumen, and bicarbonate into the intercellular space. They have a characteristic ultrastructural appearance with secretory canaliculi (deep invaginations of the surface membrane), and cytoplasmic tubulovesicles containing the acid-producing apparatus $\text{H}^+ / \text{K}^+\text{ATPase}$ (proton pump) (see Fig. 26-9). There are numerous mitochondria; in fact the parietal cell is the most mitochondria rich cell in the body. When the parietal cell is stimulated,
hormone-secreting cells are present in various proportions throughout the gastric mucosa (Fig. 26-11). Histologic analysis suggests that in the normal stomach, 13% of the epithelial cells are oxyntic (parietal) cells, 44% are chief (zymogenic) cells, 40% are mucous cells, and 3% are endocrine cells. In general, the antrum produces gastrin but not acid, and the proximal stomach produces acid but not gastrin. The border between the corpus and antrum migrates proximally with age (especially on the lesser curvature side of the stomach).

Deep to the muscularis mucosa is the submucosa, which is rich in branching blood vessels, lymphatics, collagen, various inflammatory cells, and nerve fibers and ganglion cells of Meissner’s autonomic submucosal plexus. The collagen-rich submucosa gives strength to GI anastomoses. The mucosa and submucosa are folded into the grossly visible gastric rugae, which tend to flatten out as the stomach becomes distended.

Below the submucosa is the thick muscularis propria (also referred to as the muscularis externa), which consists of an incomplete inner oblique layer, a complete middle circular layer (continuous with the esophageal circular muscle and the circular muscle of the pylorus), and a complete outer longitudinal layer (continuous with the longitudinal layer of the esophagus and duodenum). Within the muscularis propria is the rich network of autonomic ganglia and nerves that make up Auerbach’s myenteric plexus. Specialized pacemaker cells, the interstitial cells of Cajal (ICC), also are present.

The outer layer of the stomach is the serosa, also known as the visceral peritoneum. This layer provides significant tensile strength to gastric anastomoses. When tumors originating in the mucosa penetrate and breach the serosa, microscopic or gross peritoneal metastases are common, presumably from shedding of tumor cells that would not have occurred if the serosa had not been penetrated. In this way, the serosa may be thought of as an outer envelope of the stomach.

**PHYSIOLOGY**

The stomach stores food and facilitates digestion through a variety of secretory and motor functions. Important secretory functions include the production of acid, pepsin, intrinsic factor, mucus, and a variety of GI hormones. Important motor functions include food storage (receptive relaxation and accommodation), grinding and mixing, controlled emptying of ingested food, and periodic interprandial “housekeeping.”

**Acid Secretion**

Hydrochloric acid in the stomach hastens both the physical and (with pepsin) the biochemical breakdown of ingested food. In an acidic environment, pepsin and acid facilitate proteolysis. Gastric acid also inhibits the proliferation of ingested pathogens, which protects against both infectious gastroenteritis and intestinal bacterial overgrowth. Long-term acid suppression with proton pump inhibitors (PPIs) has been associated with an increased risk of community acquired *Clostridium difficile* colitis and other gastroenteritis, presumably because of the absence of this protective germicidal barrier.

**Parietal Cell.** The parietal cell is stimulated to secrete acid (Fig. 26-12) when one or more of three membrane receptor types is stimulated by acetylcholine (from vagal nerve fibers), gastrin (from D cells), or histamine (from ECL cells). The enzyme H+/K+-ATPase is the proton pump. It is stored within the intracellular tubulovesicles and is the final common pathway for gastric

---

![Figure 26-8. Mammalian gastric gland from the body of the stomach.](Image)
When the parietal cell is stimulated, there is a cytoskeletal rearrangement and fusion of the tubulovesicles with the apical membrane of the secretory canaliculus. The heterodimer assembly of the enzyme subunits into the microvilli of the secretory canaliculus results in acid secretion, with extracellular potassium being exchanged for cytosolic hydrogen. Although electro-neutral, this is an energy requiring process because the hydrogen is secreted against a gradient of at least 1 million-fold, which explains why the parietal cell is packed with energy producing mitochondria. During acid production, potassium and chloride are also secreted into the apical secretory canaliculus through separate channels, providing potassium to exchange for H+ via the H+/K+-ATPase, and chloride to accompany the secreted hydrogen. At the basolateral membrane, the combined activity of various cotransporters and ion exchangers accomplishes intracellular pH regulation and electrolyte homeostasis.39

The normal human stomach contains approximately 1 billion parietal cells, and total gastric acid production is proportional to parietal cell mass. The potent acid-suppressing PPI drugs irreversibly interfere with the function of the H+/K+-ATPase molecule.

Source: From Antonioli et al.16 with permission.
Activation of calcium from intracellular stores, which leads to activation of phospholipase C via a G-protein–linked mechanism leading to increased production of inositol trisphosphate from membrane bound phospholipids. Inositol trisphosphate stimulates the release of calcium from intracellular stores, which leads to activation of protein kinases and activation of H+K+-ATPase. Histamine binds to the histamine 2 (H₂) receptor, which stimulates adenylatecyclase, also via a G-protein–linked mechanism. Activation of adenylatecyclase results in an increase in intracellular cyclic adenosine monophosphate which activates protein kinases, leading to increased levels of phosphoproteins and activation of the proton pump. Somatostatin from mucosal D cells binds to membrane receptors and inhibits the activation of adenylatecyclase through an inhibitory G protein.

**Physiologic Acid Secretion.** Food ingestion is the physiologic stimulus for acid secretion (Fig. 26-13). The acid secretory response that occurs after a meal is traditionally described in three phases: cephalic, gastric, and intestinal. The cephalic or vagal phase begins with the thought, sight, smell, and/or taste of food. These stimuli activate several cortical and hypothalamic sites (e.g., tractus solitarius, dorsal motor nucleus, and dorsal vagal complex), and signals are transmitted to the stomach by the vagal nerves. Acetylcholine is released, leading to stimulation of ECL cells and parietal cells. Although the acid secreted per unit of time in the cephalic phase is greater than in the other two phases, the cephalic phase is shorter. Thus, the cephalic phase accounts for no more than 30% of total acid secretion in response to a meal. Sham feeding (chewing and spitting) stimulates gastric acid secretion only via the cephalic phase, and results in acid secretion that is about half of that seen in response to IV pentagastrin or histamine.

When food reaches the stomach, the gastric phase of acid secretion begins. This phase lasts until the stomach is empty, and accounts for about 60% of the total acid secretion in response to a meal. The gastric phase of acid secretion has several components. Amino acids and small peptides directly stimulate antral G cells to secrete gastrin, which is carried in the bloodstream to the parietal cells and stimulates acid secretion in an endocrine fashion. In addition, proximal gastric distention

---

**Oxyntic mucosa**

**Pyloric mucosa**

These agents must be incorporated into the activated enzyme to be effective, and thus work best when taken before or during a meal (when the parietal cell is stimulated). When PPI therapy is stopped, acid secretory capability gradually returns (within days) as new H⁺/K⁺-ATPase is synthesized.

Gastrin, acetylcholine, and histamine stimulate the parietal cell to secrete hydrochloric acid (see Fig. 26-12). Gastrin binds to type B cholecystokinin (CCK) receptors, and acetylcholine binds to M₃ muscarinic receptors. Both stimulate phospholipase C via a G-protein–linked mechanism leading to increased levels of phosphoproteins and activation of adenylatecyclase, also via a G-protein–linked mechanism. Activation of adenylatecyclase results in an increase in intracellular cyclic adenosine monophosphate which activates protein kinases, leading to increased levels of phosphoproteins and activation of the proton pump. Somatostatin from mucosal D cells binds to membrane receptors and inhibits the activation of adenylatecyclase through an inhibitory G protein.

**Physiologic Acid Secretion.** Food ingestion is the physiologic stimulus for acid secretion (Fig. 26-13). The acid secretory response that occurs after a meal is traditionally described in three phases: cephalic, gastric, and intestinal. The cephalic or vagal phase begins with the thought, sight, smell, and/or taste of food. These stimuli activate several cortical and hypothalamic sites (e.g., tractus solitarius, dorsal motor nucleus, and dorsal vagal complex), and signals are transmitted to the stomach by the vagal nerves. Acetylcholine is released, leading to stimulation of ECL cells and parietal cells. Although the acid secreted per unit of time in the cephalic phase is greater than in the other two phases, the cephalic phase is shorter. Thus, the cephalic phase accounts for no more than 30% of total acid secretion in response to a meal. Sham feeding (chewing and spitting) stimulates gastric acid secretion only via the cephalic phase, and results in acid secretion that is about half of that seen in response to IV pentagastrin or histamine.

When food reaches the stomach, the gastric phase of acid secretion begins. This phase lasts until the stomach is empty, and accounts for about 60% of the total acid secretion in response to a meal. The gastric phase of acid secretion has several components. Amino acids and small peptides directly stimulate antral G cells to secrete gastrin, which is carried in the bloodstream to the parietal cells and stimulates acid secretion in an endocrine fashion. In addition, proximal gastric distention

---

**Figure 26-12.** Control of acid secretion in the parietal cell. ATP = adenosine triphosphate; cAMP = cyclic adenosine monophosphate; CCK = cholecystokinin; H₂ = histamine 2; IP₃ = inositol trisphosphate; PIP₂ = phosphatidylinositol 4,5-bisphosphate; PLC = phospholipase C. Reproduced with permission from Mercer DW, Liu TH, Castaneda A: Anatomy and physiology of the stomach, in Zuidema GD, Yeo CJ (eds): Shackelford’s Surgery of the Alimentary Tract, 5th ed., Vol. II. Philadelphia: Saunders, 2002, p 3. Copyright Elsevier.
When these defenses break down, intake supplementation by a nonenteric route. Some, and the complex is deficiency following gastric RAs) are such effective inhibitors of acid secretion, eds This explains why the histamine 2 receptor antago...4,25

stimulates acid secretion via a vagovagal reflex arc, which is abolished by truncal or HSV. Antral distention also stimulates antral gastric secretion. Acetylcholine stimulates gastrin release and gastrin stimulates histamine release from ECL cells.

The intestinal phase of gastric secretion is poorly understood. It is thought to be mediated by a hormone released from the proximal small bowel mucosa in response to luminal chyme. This phase starts when gastric emptying of ingested food begins, and continues as long as nutrients remain in the proximal small intestine. It accounts for about 10% of meal-induced acid secretion.

Interprandial basal acid secretion is 2 to 5 mEq hydrochloric acid per hour, about 10% of maximal acid output (MAO), and it is greater at night. Basal acid secretion probably contributes to the relatively low bacterial counts found in the stomach. Basal acid secretion is reduced 75% to 90% by vagotomy or H2 receptor blockade.

The pivotal role that ECL cells play in the regulation of gastric acid secretion is emphasized in Fig. 26-13. A large part of the acid stimulatory effects of both acetylcholine and gastrin are mediated by histamine released from mucosal ECL cells. H2 receptor knockout mice do not secrete acid in response to gastrin.26 This explains why the histamine 2 receptor antagonists (H2RAs) are such effective inhibitors of acid secretion, even though histamine is only one of three parietal cell stimulants. The mucosal D cell, which releases somatostatin, is also an important regulator of acid secretion. Somatostatin inhibits histamine release from ECL cells and gastrin release from antral G cells. The function of D cells is inhibited by Helicobacter pylori infection, and this leads to an exaggerated acid secretory response (see section Helicobacter pylori Infection).

Pepsinogen Secretion
The most potent physiologic stimulus for pepsinogen secretion from chief cells is food ingestion; acetylcholine is the most important mediator. Somatostatin inhibits pepsinogen secretion. Pepsinogen I is produced by chief cells in acid producing glands, whereas pepsinogen II is produced by SECs in both acid producing and gastrin producing (i.e., antral) glands. Pepsinogen is cleaved to the active pepsin enzyme in an acidic environment and is maximally active at pH 2.5, and inactive at pH >5, although pepsinogen II may be activated over a wider pH range than pepsinogen I. Pepsin catalyzes the hydrolysis of proteins and is denatured at alkaline pH.

Intrinsic Factor
Activated parietal cells secrete intrinsic factor in addition to hydrochloric acid. Presumably the stimulants are similar, but acid secretion and intrinsic factor secretion may not be linked. Intrinsic factor binds to luminal vitamin B12, and the complex is absorbed in the terminal ileum via mucosal receptors. Vitamin B12 deficiency can be life threatening, and patients with total gastrectomy or pernicious anemia (i.e., patients with no parietal cells) require B12 supplementation by a nonenteric route. Some patients develop vitamin B12 deficiency following gastric bypass, presumably because there is insufficient intrinsic factor present in the small proximal gastric pouch and oral B12 intake may be decreased. Under normal conditions, a significant excess of intrinsic factor is secreted, and acid-suppressive medication does not appear to inhibit intrinsic factor production and release.

Gastric Mucosal Barrier
The stomach’s durable resistance to autodigestion by caustic hydrochloric acid and active pepsin is intriguing. Some of the important elements of gastric barrier function and cytoprotection are listed in Table 26-3.24,25 When these defenses break down, ulceration occurs. A variety of factors are important in maintaining an intact gastric mucosal layer. The mucus and bicarbonate secreted by SECs form an unstirred mucous gel with a favorable pH gradient. Cell membranes and tight junctions prevent hydrogen

ions from gaining access to the interstitial space. Hydrogen ions that do break through are buffered by the alkaline tide created by basolateral bicarbonate secretion from stimulated parietal cells. Any sloughed or denuded SECs are rapidly replaced by migration of adjacent cells, a process known as restitution. Mucosal blood flow plays a crucial role in maintaining a healthy mucosa, providing nutrients and oxygen for the cellular functions involved in cytoprotection. “Back-diffused” hydrogen is buffered and rapidly removed by the rich blood supply. When “barrier breakers” such as bile or aspirin lead to increased back-diffusion of hydrogen ions from the lumen into the lamina propria and submucosa, there is a protective increase in mucosal blood flow. If this protective response is blocked, gross ulceration can occur. Important mediators of these protective mechanisms include prostaglandins, nitric oxide, intrinsic nerves, and peptides (e.g., calcitonin gene-related peptide, gastrin-releasing peptide [GRP], gastrin, and heat shock proteins). Sucralfate acts locally to enhance mucosal defenses. Protective reflexes involve afferent sensory neurons, and can be blocked by the application of topical anesthetics to the gastric mucosa, or the experimental destruction of the afferent sensory nerves. In addition to these local defenses, there are important protective factors in saliva, duodenal secretions, and pancreatic or biliary secretions.

**Gastric Hormones**

**Gastrin.** Gastrin is produced by antral G cells and is the major hormonal stimulant of acid secretion during the gastric phase. A variety of molecular forms exist: big gastrin (34 amino acids; G17), little gastrin (17 amino acids; G17), and mini-gastrin (14 amino acids; G14). The large majority of gastrin released by the human antrum is G17. The biologically active pentapeptide sequence at the C-terminal end of gastrin is identical to that of CCK. Luminal peptides and amino acids are the most potent stimulants of gastrin release, and luminal acid is the most potent inhibitor of gastrin secretion. The latter effect is predominantly mediated in a paracrine fashion by somatostatin released from antral D cells. Gastrin-stimulated acid secretion is significantly blocked by H2 antagonists, suggesting that the principal mediator of gastrin-stimulated acid production is histamine from mucosal ECL cells (see Fig. 26-13). In fact, chronic hypergastrinemia is associated with hyperplasia of gastric ECL cells and, rarely, gastric carcinoid. Gastrin is trophic to gastric parietal cells and to other GI mucosal cells. Important causes of hypergastrinemia include pernicious anemia, acid-suppressive medication, gastrinoma, retained antrum following distal gastrectomy and Billroth II surgery, and vagotomy.

**Somatostatin.** Somatostatin is produced by D cells located throughout the gastric mucosa. The predominant form in humans is somatostatin 14, though somatostatin 28 is present as well. The major stimulus for somatostatin release is antral acidification; acetylcholine from vagal nerve fibers inhibits its release. Somatostatin inhibits acid secretion from parietal cells and gastrin release from G cells. It also decreases histamine release from ECL cells. The proximity of the D cells to these target cells suggests that the primary effect of somatostatin is mediated in a paracrine fashion, but an endocrine (i.e., bloodstream) effect also is possible.

**Gastrin-Releasing Peptide.** GRP is the mammalian equivalent of bombesin, a hormone discovered more than two decades ago in an extract of skin from a frog. In the antrum, GRP stimulates both gastrin and somatostatin release by binding to receptors on the G and D cells. There are nerve terminals ending near the mucosa in the gastric body and antrum, which are rich in GRP immunoreactivity. When GRP is given peripherally, it stimulates acid secretion, but when it is given centrally into the cerebral ventricles of animals, it inhibits acid secretion, apparently via a pathway involving the sympathetic nervous system. GRP is a mediator of gastroprotective increased mucosal blood flow in response to luminal irritants.

**Leptin.** Leptin is a protein primarily synthesized in adipocytes. It is also made by chief cells in the stomach, the main source of leptin in the GI tract. Leptin works at least in part via vagally mediated pathways to decrease food intake in animals. Not surprisingly, leptin, a satiety signal hormone, and ghrelin, a hunger signal hormone, are both primarily synthesized in the stomach, an organ increasingly recognized as central to the mechanisms of appetite control.

**Ghrelin.** Ghrelin is a small peptide described in 1999 that is produced primarily in the stomach. Ghrelin is a potent secretagogue of pituitary growth hormone (but not adrenocorticotropic hormone, follicle-stimulating hormone, luteinizing hormone, prolactin, or thyroid-stimulating hormone). Ghrelin appears to be an orexigenic regulator of appetite (i.e., when ghrelin is elevated, appetite is stimulated, and when it is suppressed, appetite is suppressed). Resection of the primary source of this hormone (i.e., the stomach) may partly account for the anorexia and weight loss seen in some patients following gastric resection including sleeve gastrectomy (Fig. 26-14A). The gastric bypass operation, a very effective treatment for morbid obesity, has been shown by some investigators to be associated with suppression of plasma ghrelin levels (and appetite) in humans (Fig. 26-15A).

![Figure 26-14. Ghrelin levels are decreased after gastrectomy.](Reproduced with permission from Ariyasu H, Takaya K, Tagami T, et al: Stomach is a major source of circulating ghrelin, and feeding state determines plasma ghrelin-like immunoreactivity levels in humans. J Clin Endocrinol Metab. 86:4753, 2001.)
Figure 26-15. A and B. Ghrelin secretion after bariatric surgery. Some investigators have suggested that ghrelin secretion is dramatically decreased after gastric bypass. Other groups have shown statistically insignificant changes in ghrelin levels after gastric bypass, (RYGBP) but significant decreases after sleeve gastrectomy (SG). A: green = gastric bypass; blue = obese controls; red = normal weight controls; B: blue = fasting; pink = postprandial. B. Top = RYGBP; B bottom = SG. (Fig. 26-15A reproduced with permission from Cummings DE, et al: Plasma ghrelin levels after diet-induced weight loss or gastric bypass surgery. N Engl J Med 346:1623, 2002. Copyright ©2002 Massachusetts Medical Society. All rights reserved. Fig. 26-15B reproduced with permission from Karanamakos SN, et al: Weight loss, appetite suppression, and changes in fasting and postprandial ghrelin and peptide-YY levels after Roux-en-Y gastric bypass and sleeve gastrectomy: A prospective, double blind study. Ann Surg 247:401, 2008.)
 Other groups have failed to show a significant decrease in ghrelin levels following gastric bypass but have found such decreases following sleeve gastrectomy, another effective weight loss operation (Fig. 26-15B). Possibly subtle differences in operative technique, patient selection, and/or experimental conditions account for the findings that multiple studies have reported disparate results on the effect of bariatric surgery on ghrelin levels in obese patients. Obviously appetite control is complex with redundant and overlapping orexigenic and anorexigenic pathways and signals.\(^{36,37}\)

### Gastric Motility and Emptying

Gastric motor function has several purposes.\(^{13,32,33,34}\) Interprandial motor activity clears the stomach of undigested debris, sloughed cells, and mucus. When feeding begins, the stomach relaxes to accommodate the meal. Regulated motor activity then breaks down the food into small particles and controls the output into the duodenum. The stomach accomplishes these functions by coordinated smooth muscle relaxation and contraction of the various gastric segments (proximal, distal, and pyloric). Smooth muscle myoelectric potentials are translated into muscular activity, which is modulated by extrinsic and intrinsic innervation and hormones. The mechanisms by which gastric distention is translated into a neurohormonal satiety signal have only been partially elucidated.\(^{36,37}\)

#### Intrinsic Gastric Innervation

The extrinsic parasympathetic and sympathetic gastric innervation was discussed previously under Innervation. The intrinsic innervation consists of ganglia and nerves that constitute the enteric nervous system (Fig. 26-16).\(^{35}\) There are a variety of neurotransmitters, which are generally grouped as excitatory (augment muscular activity) and inhibitory (decrease muscular activity). Important excitatory neurotransmitters include acetylcholine, the tachykinins, substance P, and neuropeptide A. Important inhibitory neurotransmitters include nitric oxide (NO) and vasoactive intestinal peptide (VIP). Serotonin has been shown to modulate both contraction and relaxation. A variety of other molecules affect motility, including GRP, histamine, neuropeptide Y, norepinephrine, and endogenous opioids.

Specialized cells in the muscularis propria also are important modulators of GI motility. These cells, called interstitial cells of Cajal, are distinguishable histologically from neurons and myocytes, and appear to amplify both cholinergic excitatory and nitrergic inhibitory input to the smooth muscle of the stomach and intestine.\(^{38}\) They are thought to be the cell of origin for gastrointestinal stromal tumors (GISTs) which are the most common mesenchymal neoplasm in the GI tract.

#### Segmental Gastric Motility

In general, the proximal stomach serves a short-term food storage function and helps regulate basal intra-gastric tone, and the distal stomach mixes and grinds the food. The pylorus helps the latter process when closed, facilitating retropulsion of the solid food bolus back into the body of the stomach for additional breakdown. The pylorus opens intermittently to allow metered emptying of liquids and small solid particles into the duodenum.

Most of the motor activity of the proximal stomach consists of slow tonic contractions and relaxations, lasting up to 5 minutes. This activity is the main determinant of basal intra-gastric pressure, an important determinant of liquid emptying. Rapid phasic contractions may be superimposed on the slower tonic motor activity. When food is ingested, intra-gastric pressure falls as the proximal stomach relaxes. This proximal relaxation is mediated by two important vagovagal reflexes: receptive relaxation and gastric accommodation. Receptive relaxation refers to the reduction in proximal gastric tone associated with the act of swallowing. This occurs before the food reaches the stomach, and can be reproduced by mechanical stimulation of the pharynx or esophagus. Gastric accommodation refers to the proximal gastric relaxation associated with distention of the stomach. Accommodation is mediated through stretch receptors in the gastric wall and does not require esophageal or pharyngeal stimulation. Because both of these reflexes are mediated by afferent and efferent vagal fibers, they are significantly altered by truncal and highly selective vagotomy. Both these operations result in decreased gastric compliance, shifting the volume/pressure curve to the left. That is, interference with normal receptive relaxation and/or accommodation results in decreased gastric compliance, such that for any given amount of

food or liquid ingested, the intragastric pressure is greater. This may increase the rate of liquid emptying, perhaps contributing to dumping symptoms after vagotomy.

NO and VIP are the principal mediators of proximal gastric relaxation. But a variety of other agents increase proximal gastric relaxation and compliance, including dopamine, gastrin, CCK, secretin, GRP, and glucagon. Proximal gastric tone also is decreased by duodenal distention, colonic distention, and ileal perfusion with glucose (ileal brake).

The distal stomach breaks up solid food and is the main determinant of gastric emptying of solids. Slow waves of myoelectric depolarization sweep down the distal stomach at a rate of about three per minute. These waves originate from the proximal gastric pacemaker, high on the greater curvature. The pacing cells may be interstitial cells of Cajal, which have been shown to have a similar function in the small intestine and colon. Most of these myoelectric waves are below the threshold for smooth muscle contraction in the quiescent state, and thus are associated with negligible changes in pressure. Neural and/or hormonal input, which increases the plateau phase of the action potential, can trigger muscle contraction, resulting in a peristaltic wave associated with the electrical slow wave, and of the same frequency (three per minute) (Fig. 26-17). It is possible that implantable gastric pacemakers benefit some patients with gastroparesis by favorably impacting this myoelectric coupling.

During fasting, distal gastric motor activity is controlled by the migrating motor complex (MMC), the “gastrointestinal housekeeper” (Fig. 26-18). The purported function of the MMC is to sweep along any undigested food, debris, sloughed cells, and mucus after the fed phase of digestion is complete. The MMC lasts approximately 100 minutes (longer at night, shorter during daytime) and is divided into four phases. Phase I (about half the length of the entire cycle) is a period of relative motor inactivity. High-amplitude muscular contractions do not occur in phase I of the MMC. Phase II (about 25% of the entire MMC cycle) consists of some irregular, high-amplitude, generally nonpropulsive contractions. Phase III, a period of intense, regular, (about three per minute) propulsive contractions, only lasts about 5 to 10 minutes. Most phase III complexes of the GI MMC begin in the stomach, and the frequency approximates that of the myoelectric gastric slow wave. Phase IV is a transition period.

Neurohormonal control of the MMC is poorly understood, but it appears that different phases are regulated by different mechanisms. For example, vagotomy abolishes phase II of the gastric MMC but has little influence on phase III that persists.

Figure 26-17. The relationship between intracellular electrical activity and muscle cell contraction. Note that contractile activity is always associated with electrical activity, but the converse is not so. During mechanical quiescence, there are regular depolarizations that do not reach threshold. In the stimulated state, the threshold for contraction is reached, and motor activity is demonstrable. [Reproduced with permission from Kim CH. Electrical activity of the stomach: clinical implications. Mayo Clin Proc. 61:205, 1986.]

even in the autotransplanted stomach, totally devoid of extrinsic neural input. This suggests that phase III is regulated by intrinsic nerves and/or hormones. Indeed, the initiation of phase III of the MMC in the distal stomach corresponds temporally to elevation in serum levels of motilin, a hormone produced in the duodenal mucosa. Resection of the duodenum abolishes distal gastric phase III in dogs, and resection of the duodenum in humans (e.g., with pancreatecoduodenectomy, the Whipple procedure) commonly results in early postoperative delayed gastric emptying. There are clearly motilin receptors on antral smooth muscle and nerves. Other modulators of gastric MMC activity include NO, endogenous opioids, intrinsic cholinergic and adrenergic nerves, and duodenal pH.

Feeding abolishes the MMC and leads to the fed motor pattern. The fed motor pattern of gastric activity starts within 10 minutes of food ingestion and persists until all the food has left the stomach. The neurohormonal initiator of this change is unknown, but CCK and the vagus appear to play some role. Sham feeding transiently induces antral motor activity resembling the fed motor pattern, and this is blocked by the CCK receptor antagonist loxiglumide. Gastric motility during the fed pattern resembles phase II of the MMC, with irregular but continuous phasic contractions of the distal stomach. During the fed state, about half of the myoelectric slow waves are associated with strong distal gastric contractions. Some are prograde and some are retrograde, serving to mix and grind the solid components of the meal. The magnitude of gastric contractions and the duration of the pattern are influenced by the consistency and composition of the meal.

The pylorus functions as an effective regulator of gastric emptying and an effective barrier to duodenogastric reflux. Bypass, transection, or resection of the pylorus may lead to uncontrolled gastric emptying of food and the dumping syndrome (see Postgastrectomy Problems). Pyloric dysfunction or disruption may also result in uncontrolled entry of duodenal contents into the stomach. Perfusion of the duodenum with lipids, glucose, amino acids, hypertonic saline, or hydrochloric acid results in closure of the pylorus and decreased transpyloric flow. Ileal perfusion with fat has the same effect. A variety of neurohumoral pathways are involved with these physiologic responses, and there is evidence that different pathways may be involved for different stimuli.

The pylorus is readily apparent grossly as a thick ring of muscle and connective tissue. The density of nerve tissue in the pyloric smooth muscle is several folds higher than in the antrum, with increased numbers of neurons staining positive for substance P, neuropeptide Y, VIP, and galanin. Interstitial cells of Cajal are more closely associated with pyloric myocytes, and the myoelectric slow wave of the pylorus has the same frequency as that seen in the distal stomach. The motor activity of the pylorus is both tonic and phasic. During phase III of the MMC, the pylorus is open as gastric contents are swept into the duodenum. During the fed phase, the pylorus is closed most of the time. It relaxes intermittently, usually in synchronization with lower-amplitude, minor antral contractions. The higher-amplitude, more major antral contractions are usually met with a closed pylorus, facilitating retropulsion and further grinding of food.

Modulation of pyloric motor activity is complex. There is evidence of both inhibitory and excitatory vagal pathways. Some contractile vagal effects are mediated by opioid pathways, because they are blocked by naloxone. Electrical stimulation of the duodenum causes the pylorus to contract, whereas electrical stimulation of the antrum causes pyloric relaxation. Nitric oxide is an important mediator of pyloric relaxation. Other molecules that may play a physiologic role in controlling pyloric smooth muscle include serotonin, VIP, prostaglandin E2, and galanin (pyloric relaxation); and histamine, CCK, and secretin (pyloric contraction).

**Gastric Emptying.** The control of gastric emptying is complex. In general, liquid emptying is faster than solid emptying. Osmolarity, acidity, caloric content, nutrient composition, and particle size are important modulators of gastric emptying. Stimulation of duodenal osmoreceptors, glucoseceptors, and pH receptors clearly inhibits gastric emptying by a variety of neurohumoral mechanisms. CCK has been consistently shown to inhibit gastric emptying at physiologic doses (Fig. 26-19). Recently, it has been noted that the anorexigenic hormone leptin, secreted by fat and gastric mucosa, inhibits gastric emptying, perhaps through the same pathway as CCK (which also has properties of a satiety hormone). The orexigenic hormone ghrelin has the opposite effect.

**Liquid Emptying.** The gastric emptying of water or isotonic saline follows first-order kinetics, with a half-emptying time around 12 minutes. Thus, if one drinks 200 mL of water, about 100 mL enters the duodenum by 12 minutes, whereas if one drinks 400 mL of water, about 200 mL enters the duodenum by 12 minutes. This emptying pattern of liquids is modified considerably as the caloric density, osmolarity, and nutrient composition of the liquid changes (Fig. 26-20). Up to an osmolarity of about 1 M, liquid emptying occurs at a rate of about 200 kcal per hour. Duodenal osmoreceptors and hormones (e.g., secretin and VIP) are important modulators of liquid gastric emptying. Generally, liquid emptying is delayed in the supine position.

Traditionally, liquid emptying has been attributed to the activity of the proximal stomach, but it is probably more complicated than previously thought. Clearly, receptive relaxation and gastric accommodation play a role in gastric emptying of liquids. Patients with a denervated (e.g., vagotomized),

![Figure 26-19](image-url) Cholecystokinin (CCK) inhibits gastric emptying. [Reproduced with permission from Covasa M, Ritter RC: Adaptation to high-fat diet reduces inhibition of gastric emptying by CCK and intestinal oleate. Am J Physiol Regulatory Integrative Comp Physiol 278:R166, 2000.]

Figure 26-20. Nutrient composition and caloric density affect
liquid gastric emptying. Glucose solution (purple circles), the least
calorically dense, emptied the fastest. Other more calorically dense
solutions, such as milk protein (green triangles) and peptide hydrolysates (red circles and blue triangles), emptied slower. [Reproduced

resected, or plicated (e.g., fundoplication) proximal stomach
have decreased gastric compliance and may show accelerated
gastric emptying of liquids.
Some observations suggest an active role for the distal
stomach in liquid emptying. For instance even if the proximal
intragastric pressure is lower than duodenal pressure, normal
gastric emptying of liquids can occur. Also, diabetic patients
may have normal proximal gastric motor function and profoundly delayed gastric emptying of liquids. Indeed, antral
contractile activity does correlate with liquid gastric emptying,
and this distal gastric activity appears to vary with the nutrient
composition and caloric content of the liquid meal. Depending on the circumstances, distal gastric motor activity can promote or inhibit gastric emptying of liquids. Distal gastrectomy
and pyloric stenting both obviously interfere with distal gastric
motor activity, and both accelerate the initial rapid phase of liquid gastric emptying.

Solid Emptying. Normally, the half-time of solid gastric
emptying is less than 2 hours. Unlike liquids, which display an
initial rapid phase followed by a slower linear phase of emptying, solids have an initial lag phase during which little emptying of solids occurs. It is during this phase that much of the
grinding and mixing occurs. A linear emptying phase follows,
during which the smaller particles are metered out to the duodenum. Solid gastric emptying is a function of meal particle size,
caloric content, and composition (especially fat). When liquids
and solids are ingested together, the liquids empty first. Solids
are stored in the fundus and delivered to the distal stomach at
constant rates for grinding. Liquids also are sequestered in the
fundus, but they appear to be readily delivered to the distal
stomach for early emptying. The larger the solid component of
the meal, the slower the liquid emptying. Patients bothered by

dumping syndrome are advised to limit the amount of liquid
consumed with the solid meal, taking advantage of this effect.
Three prokinetic agents are commonly used to treat delayed
gastric emptying. Typical doses and mechanism of action are
shown in Table 26-4.

DIAGNOSIS OF GASTRIC DISEASE
Signs and Symptoms

The most common symptoms of gastric disease are pain, weight
loss, early satiety, and anorexia. Nausea, vomiting, bloating, and
anemia also are frequent complaints. Several of these symptoms
(pain, bloating, nausea, and early satiety) are often described by
physicians as dyspepsia, synonymous with the common nonmedical term indigestion. Common causes of dyspepsia include
gastroesophageal reflux disease (GERD) and disorders of the
stomach, gallbladder, and pancreas. Although none of the above
symptoms alone is specific for gastric disease, when elicited
in the context of a careful history and physical examination,
they point to a differential diagnosis, which can be refined with
certain tests.

Diagnostic Tests
Esophagogastroduodenoscopy. Patients with one or more of
the alarm symptoms listed in Table 26-5 should undergo expeditious upper endoscopy. Esophagogastroduodenoscopy (EGD) is
a safe and accurate outpatient procedure performed under conscious sedation.38 Smaller flexible scopes with excellent optics
and a working channel are easily passed transnasally in the
unsedated patient. Following an 8-hour fast, the flexible scope
is advanced under direct vision into the esophagus, stomach,
and duodenum. The fundus and GE junction are inspected by
retroflexing the scope. To rule out cancer with a high degree of
accuracy, all patients with gastric ulcer diagnosed on upper GI
series or found at EGD should have multiple biopsy specimens
of the base and rim of the lesion. Brush cytology also should

be considered. Gastritis should be biopsied both for histologic examination and for a tissue urease test to rule out the presence of *H. pylori*. If Helicobacter infection is detected, it should probably be treated because of the etiologic association with peptic ulcers, mucosa-associated lymphoid tissue (MALT), and gastric cancer. The most serious complications of EGD are perforation (which is rare, but can occur anywhere from the cervical esophagus to the duodenum), aspiration, and respiratory depression from excessive sedation. Although EGD is a more sensitive test than double-contrast upper GI series, these modalities should be considered complementary rather than mutually exclusive.

**Radiologic Tests.** Plain abdominal X-rays may be helpful in the diagnosis of gastric perforation (pneumoperitoneum) or delayed gastric emptying (large air-fluid level).

- **Double-contrast upper GI series** may be better than EGD at elucidating gastric diverticula, fistula, tortuosity, stricture location, and size of hiatal hernia. Although there are radiologic characteristics of ulcers that suggest the presence or absence of malignancy, gastric ulcers always require adequate biopsy.

**Computed Tomographic Scanning and Magnetic Resonance Imaging.** Usually, significant gastric disease can be diagnosed without these sophisticated imaging studies. However, one or the other should be part of the routine staging work-up for most patients with a malignant gastric tumor. Magnetic resonance imaging (MRI) may prove clinically useful as a quantitative test for gastric emptying, and may even hold some promise for the analysis of myoelectric derangements in patients with gastroparesis. Virtual gastroscopy using multi detector CT scan or MRI is not yet widely used but these techniques may prove useful for screening and staging of gastric disease.\(^\text{40-41}\) (Fig. 26-21).

Arteriography may be helpful in the occasional poor-risk patient with exsanguinating gastric hemorrhage, or in the patient with occult gastric bleeding.

**Endoscopic Ultrasound.** Endoscopic ultrasound (EUS) is useful in the evaluation and management of some gastric lesions.\(^\text{42-44}\) Local staging of gastric adenocarcinoma with EUS is quite accurate, and this modality can be used to plan therapy. At some centers, patients with transmural and/or node positive adenocarcinoma of the stomach are considered for preoperative (neoadjuvant) chemoradiation therapy. EUS is the best way to clinically stage these patients locoregionally. Suspicious nodes can be sampled with EUS-guided endoscopic needle biopsy. Malignant tumors that are confined to the mucosa on EUS may be amenable to endoscopic mucosal resection (EMR). EUS also can be used to assess tumor response to chemotherapy. Submucosal masses are commonly discovered during routine EGD. Large submucosal masses should be resected because of the risk of malignancy, but observation may be appropriate for some small submucosal masses (e.g., lipoma or small GIST). There are endoscopic characteristics of benign and malignant mesenchymal tumors, and thus, EUS can provide reassurance, but no guarantee, that small lesions under observation are probably benign. Submucosal varices also can be assessed by EUS.

**Gastric Secretory Analysis.** Analysis of gastric acid output requires gastric intubation, and it is performed infrequently nowadays. This test may be useful in the evaluation of patients with hypergastrinemia, including the Zollinger-Ellison syndrome (ZES), patients with refractory ulcer or GERD, and patients with recurrent ulcer after operation. Historically, gastric analysis was performed most commonly to test for the adequacy of vagotomy in postoperative patients with recurrent or persistent ulcer. Now this can be done by assessing peripheral pancreatic polypeptide levels in response to sham feeding.\(^\text{45}\) A 50% increase in pancreatic polypeptide within 30 minutes of sham feeding suggests vagal integrity.

Normal basal acid output (BAO) is greater than 5 mEq/h. MAO is the average of the two final stimulated 15-minute periods and is usually 10 to 15 mEq/h. Peak acid output is defined as the highest of the four stimulated periods. Patients with a gastrinoma commonly have a high BAO, often above 30 mEq/h, but consistently above 15 mEq/h unless there has been previous vagotomy or gastric resection. In patients with gastrinoma, the ratio of BAO to MAO exceeds 0.6. Normal acid output in the patient prescribed acid-suppressive medication usually means that the patient is noncompliant. To assess acid-secretory capacity in the absence of medication effect, \(\text{H}_2\) blockers and PPIs should be withheld before gastric analysis.

**Scintigraphy.** The standard scintigraphic evaluation of gastric emptying involves the ingestion of a test meal with one or two isotopes, and scanning the patient under a gamma camera. A curve for liquid and solid emptying is plotted, and the half-time calculated. Normal standards exist for each facility. Duodenogastric reflux can be quantitated by the IV administration of hepatobiliary iminodiacetic acid (HIDA scan), which is concentrated and excreted by the liver into the duodenum. Software allows a semiquantitative assessment of how much of the isotope refluxes into the stomach. Positron emission tomography (PET) scan or CT/PET scan may be useful in staging certain patients with gastric malignancy.

**Tests for Helicobacter pylori.** A variety of tests can help the clinician to determine whether the patient has active *H. pylori* infection.\(^\text{46}\) The predictive value (positive and negative) of any of these tests when used as a screening tool depends on the prevalence of *H. pylori* infection in the screened population. A positive test is quite accurate in predicting *H. pylori* infection, but a negative test is characteristically unreliable. Thus, in the appropriate clinical setting, treatment for *H. pylori* should be initiated on the basis of a positive test, but not necessarily withheld if the test is negative. Because of the association between *H. pylori* infection and gastric lymphoma and carcinoma, many clinicians recommend treating *Helicobacter* infection when the diagnosis is made.

A positive serologic test is presumptive evidence of active infection if the patient has never been treated for *H. pylori*. Histologic examination of an antral mucosal biopsy using special stains is the gold standard test. Other sensitive tests include commercially available rapid urease tests, which assay for the presence of urease in mucosal biopsy specimens (strong presumptive evidence of infection). Urease is an omnipresent enzyme in *H. pylori* strains that colonize the gastric mucosa. The labeled carbon-13 urea breath test has become the standard test to confirm eradication of *H. pylori* following appropriate treatment.\(^\text{47}\) In this test, the patient ingests urea labeled with nonradioactive \(\text{C}^1\text{H}_{13}\). The labeled urea is acted upon by the urease present in the *H. pylori* and converted into ammonia and carbon dioxide. The radiolabeled carbon dioxide is excreted from the lungs and can be detected in the expired air (Fig. 26-22). It also can be detected in a blood sample. The fecal antigen test also is quite sensitive and specific for active *H. pylori* infection and may prove more practical in confirming a cure.
Figure 26-21. Conventional double-contrast barium study (A) shows a focal protruding mass (arrow) on the gastric fundus. Axial computed tomographic scan (B) also shows a protruding polyp (arrow). The three dimensional computed tomographic gastrographic images in the transparent (C) and virtual endoscopic (D) modes show an elevated lesion on the gastric fundus (arrows). Photograph of the total gastrectomy specimen (E) shows a well-demarcated polypoid mass (arrow); this lesion was confirmed as early gastric carcinoma type I on microscopic examination (not shown). (Reproduced with permission from Shin KS, et al: Three-dimensional MDCT gastrography compared with axial CT for the detection of early gastric cancer. J Comput Assist Tomogr 31:741, 2007.)
Antroduodenal Motility Testing and Electrogastrography. Antroduodenal motility testing and electrogastrography (EGG) are performed in specialized centers and may be useful in the evaluation of the patient with abnormal epigastric symptoms. EGG consists of the transcutaneous recording of gastric myoelectric activity. Antroduodenal motility testing is done with a tube placed transnasally or transorally into the distal duodenum. There are pressure-recording sensors extending from the stomach to the distal duodenum. The combination of these two tests together with scintigraphy provides a thorough assessment of gastric motility.

PEPTIC ULCER DISEASE

Peptic ulcers are focal defects in the gastric or duodenal mucosa that extend into the submucosa or deeper. They may be acute or chronic and, ultimately, are caused by an imbalance between mucosal defenses and acid/peptic injury (Fig. 26-23). Peptic ulcer remains a common outpatient diagnosis, but the number of physician visits, hospital admissions, and elective operations for PUD has decreased steadily and dramatically over the past three decades. Interestingly, the start of these trends all predated the use of 

These epidemiologic changes probably represent the net effect of several factors, including (beneficially) decreased prevalence of 

PUD is one of the most common GI disorders in the United States with a prevalence of about 2%, and a lifetime cumulative prevalence of about 10%, peaking around age 70 years. The costs of PUD, including lost work time and productivity, are estimated to be above $8 billion per year in the United States. In 1998, approximately 1.5% of all Medicare hospital costs were spent treating PUD, and the crude mortality rate for peptic ulcer was 1.7 per 100,000 individuals. Using the National Inpatient Sample, it can be estimated that the mortality rate in patients hospitalized in 2006 with duodenal ulcer was 3.7% compared to 2.1% for gastric ulcer. Recent studies have shown an increase in the rates of hospitalization and mortality in elderly patients for the peptic ulcer complications of bleeding and perforation. This may be due in part to the increasingly common use of NSAIDs and aspirin in this elderly cohort, many of whom also have 

Pathophysiology and Etiology

A variety of factors may contribute to the development of PUD. Although it is now recognized that the large majority of duodenal and gastric ulcers are caused by 

...
result in a duodenal or gastric ulcer in the setting of normal mucosal defenses.

Elimination of *H. pylori* infection or NSAID use is important for optimal ulcer healing, and perhaps is even more important in preventing ulcer recurrence and/or complications. A variety of other diseases are known to cause peptic ulcer, including ZES (gastrinoma), antral G-cell hyperfunction and/or hyperplasia, systemic mastocytosis, trauma, burns, and major physiologic stress. Other causative agents include drugs (all NSAIDs, aspirin, and cocaine), smoking, and psychologic stress. In the United States, probably more than 90% of serious peptic ulcer complications can be attributed to *H. pylori* infection, NSAID use, and/or cigarette smoking.

**Helicobacter pylori Infection.** With specialized flagella and a rich supply of urease, *H. pylori* is uniquely equipped for survival in the hostile environment of the stomach. About 50% of the world’s population is infected with *H. pylori*, a major cause of chronic gastritis. The same sequence of inflammation to metaplasia to dysplasia to carcinoma, that is well known to occur in the esophagus from reflux-induced inflammation (and in the colon from inflammatory bowel disease), is now increasingly well recognized to occur in the stomach with *Helicobacter*-induced gastritis. The influence of prolonged acid suppression with PPIs or H₂RAs on these esophagogastric processes is largely unknown. *Helicobacter* also clearly has an etiologic role in the development of gastric lymphoma.

The organism possesses the enzyme urease, which converts urea into ammonia and bicarbonate, thus creating an environment around the bacteria that buffers the acid secreted by the stomach. The ammonia is damaging to the surface epithelial cells. Mutant strains of *H. pylori* that do not produce urease are unable to colonize the stomach. The organism lives in the mucus layer atop the gastric SECs, and some attach to these cells (Fig. 26-25). Apparently *Helicobacter* strains that lack flagella are unable to navigate through the unstirred mucus layer to get to the apical membrane of the SEC for attachment, and are nonpathogenic. One of the mechanisms by which *Helicobacter* causes gastric injury may be through a disturbance in gastric acid secretion. This is due, in part, to the inhibitory effect that *H. pylori* exerts on antral D cells that secrete somatostatin, a potent inhibitor of antral G-cell gastrin production. *H. pylori* infection is associated with decreased levels of somatostatin, decreased
somatostatin messenger RNA production, and fewer somatostatin-producing D cells. These effects are probably mediated by \( H. pylori \)-induced local alkalization of the antrum (antral acidification is the most potent antagonist to antral gastrin secretion), and \( H. pylori \)-mediated increases in other local mediators and cytokines. The result is hypergastrinemia and acid hypersecretion (Fig. 26-26). This hypergastrinemia presumably leads to the parietal cell hyperplasia seen in many patients with duodenal ulcer. The acid hypersecretion and the antral gastritis are thought to lead to antral epithelial metaplasia in the postpyloric duodenum. This duodenal metaplasia allows \( H. pylori \) to colonize the duodenal mucosa and, in these patients, the risk of developing a duodenal ulcer increases 50-fold. When \( H. pylori \) colonizes the duodenum, there is a significant decrease in acid-stimulated duodenal bicarbonate release. When \( H. pylori \) infection is successfully treated, acid secretory physiology tends to normalize. Other mechanisms whereby \( H. pylori \) can induce gastroduodenal mucosal injury include the production of toxins (vacA and cagA), local elaboration of cytokines (particularly interleukin-8) by infected mucosa, recruitment of inflammatory cells and release of inflammatory mediators, recruitment and activation of local immune factors, and increased apoptosis (Fig. 26-27). The net effect is a weakening of mucosal defenses. The mechanism by which the helicobacter organism avoids recognition and destruction by the mucosal immune system is a topic of interest and active research.

The evidence supporting the central role of \( H. pylori \) in the pathophysiology of PUD is strong. Patients with \( H. pylori \) infection and antral gastritis are three and one-half times more likely to develop PUD than patients without \( H. pylori \) infection. Up to 90% of patients with duodenal ulcers, and 70% to 90% of patients with gastric ulcers, have \( H. pylori \) infection. It is clear from multiple randomized prospective studies that curing \( H. pylori \) infection dramatically alters the natural history of PUD, decreasing the recurrent ulcer rate from more than 75% in patients treated with a course of acid-suppressive therapy alone (in whom \( H. pylori \) is not eradicated) to less than 20% in patients treated with a course of antibacterial therapy (Fig. 26-28).

Obviously, other factors are involved in the etiology of PUD because many patients colonized with \( H. pylori \) do not get peptic ulcer disease, and many patients with peptic ulcer disease do not have \( H. pylori \) infection. These observations notwithstanding, it is clear from a variety of well-designed laboratory, clinical, and epidemiologic studies that \( H. pylori \) is indubitably an important factor in the development and recurrence of PUD. \( H. pylori \) also plays an etiologic role in gastric cancer and lymphoma.

**Acid Secretion and Peptic Ulcer.** A variety of abnormalities related to mucosal acid exposure have been described in patients with duodenal ulcer (Fig. 26-29). Although duodenal ulcer patients as a group have a higher mean BAO and mean MAO compared to normal controls, many duodenal ulcer patients have basal and peak acid outputs in the normal range, and there is no correlation between acid secretion and the severity of the ulcer disease. As a group, duodenal ulcer patients produce more acid than normal controls in response to any known acid secretory stimulus. Although they usually have normal fasting serum gastrin levels, DU patients often produce more gastric acid at any given dose of gastrin than controls. Considering that many duodenal ulcer patients do produce excessive gastric acid, it has been argued that a “normal” fasting gastrin level in these patients is inappropriately high, and that there is an impaired feedback mechanism, especially in light of the apparently increased sensitivity of the parietal cell mass to gastrin. Many of these long-standing observations now seem reasonable in light of recently gained understanding of the perturbations in acid and gastrin secretion associated with \( H. pylori \) infection. Some patients with duodenal ulcer also have increased rates of gastric emptying that deliver an increased acid load per unit of time to the duodenum. Finally, the buffering capacity of the duodenum in many patients with duodenal ulcer is compromised due to decreased duodenal bicarbonate secretion.

In patients with gastric ulcer, acid secretion is variable. Currently, five types of gastric ulcer are described, although the original Johnson classification contained three types (Fig. 26-30). The most common, Johnson type I gastric ulcer, is typically located near the angularis incisura on the lesser curvature, close to the border between antral and corpus mucosa. Patients with type I gastric ulcer usually have normal or decreased...
acid secretion. Type II gastric ulcer is associated with active or quiescent duodenal ulcer disease, and type III gastric ulcer is prepyloric ulcer disease. Both type II and type III gastric ulcers are associated with normal or increased gastric acid secretion. Type IV gastric ulcers occur near the GE junction, and acid secretion is normal or below normal. Type V gastric ulcers are medication induced and may occur anywhere in the stomach. Patients with gastric ulcers may have weak mucosal defenses that permit an abnormal amount of injurious acid back-diffusion into the mucosa. Duodenogastric reflux may play a role in...
weakening the gastric mucosal defenses, and a variety of components in duodenal juice, including bile, lysolecithin, and pancreatic juice, have been shown to cause injury and inflammation in the gastric mucosa. NSAIDs and aspirin have similar effects. Although chronic gastric ulcer usually is associated with surrounding gastritis, it is unproven that the latter leads to the former.

**Nonsteroidal Anti-Inflammatory Drugs in Peptic Ulcer Disease.** Chronic use of NSAIDs (including aspirin) increases the risk of peptic ulcer disease about 5-fold and upper GI bleeding about 4-fold.60,61 Complications of PUD (specifically hemorrhage and perforation) are much more common in patients...
taking NSAIDs. More than half of patients who present with peptic ulcer hemorrhage or perforation report the recent use of NSAIDs, including aspirin. Many of these patients remain asymptomatic until they develop these life-threatening complications.

The overall risk of significant serious adverse GI events in patients taking NSAIDs is more than three times that of controls (Table 26-6). This risk increases to five times in patients more than age 60 years old. In elderly patients taking NSAIDs, the likelihood that they will require an operation related to a GI complication is 10 times that of the control group, and the risk that they will die from a GI cause is about four and one-half times higher. This problem is put into perspective when one realizes that approximately 20 million patients in the United States take NSAIDs on a regular basis; probably more regularly than aspirin. Persons who take NSAIDs also have a higher hospitalization rate for serious GI events than those who do not.

Factors that clearly put patients at increased risk for NSAID-induced GI complications include age >60, prior GI event, high NSAID dose, concurrent steroid intake, and concurrent anticoagulant intake. ANY patient taking NSAIDs or aspirin who has one or more of these risk factors should receive concomitant acid suppressing medication. Table 26-7. High dose H2 blockers have been shown to be less effective than PPIs in preventing GI complications in these high risk patients on antiplatelet therapy, but clearly they are better than no acid suppression.

**Smoking, Stress, and Other Factors.** Epidemiologic studies suggest that smokers are about twice as likely to develop PUD as nonsmokers. Smoking increases gastric acid secretion and duodenogastric reflux. Smoking decreases both gastroduodenal prostaglandin production and pancreaticoduodenal bicarbonate production. These observations may be related, and any or all could explain the observed association between smoking and PUD.

Although difficult to measure, both physiologic and psychologic stress undoubtedly play a role in the development of peptic ulcer in some patients. In 1842, Curling described duodenal ulcer and/or duodenitis in burn patients. Decades later, Cushing described the appearance of acute peptic ulceration in patients with head trauma (Cushing’s ulcer). Even the ancients recognized the undeniable links between PUD and stress. Patients still present with ulcer complications (bleeding, perforation, and obstruction) that are seemingly exacerbated by stressful life events. The use of crack cocaine has been linked to juxtapyloric peptic ulcers with a propensity to perforate. Alcohol is commonly mentioned as a risk factor for PUD, but confirmatory data are lacking.

- MUCOSA and VIGOR trials included only rheumatoid arthritis patients; CLASS trial included osteoarthritis (73%) and rheumatoid arthritis (27%).
- Incidence for MUCOSA trial represents doubling of results provided at 6 months (although median follow-up was <6 months). Incidences for VIGOR and CLASS trials represent rates per 100 patient-years, although VIGOR median follow-up was 9 months and CLASS data include only the first 6 months of the study.
- Includes perforations, obstructions, bleeding, and uncomplicated ulcers discovered on clinically indicated work-up.
- Includes perforation, obstruction, bleeding (documented due to ulcer or erosions in MUCOSA and CLASS; major bleeding in VIGOR).
- 21% of patients in CLASS study were taking low-dose aspirin.

Note: All differences between controls and study drugs were significant except clinical upper GI events in overall CLASS study (P = .09).

### Table 26-7

**Patients taking NSAIDs or aspirin need concomitant acid suppressing medication if any of the following risk factors is present**

- Age over 60
- History of acid/peptic disease
- Concurrent steroid intake
- Concurrent anticoagulant intake
- High-dose NSAID or acetylsalicylic acid
Clinical Manifestations

More than 90% of patients with PUD complain of abdominal pain. The pain is typically nonradiating, burning in quality, and located in the epigastrium. The mechanism of the pain is unclear. Patients with duodenal ulcer often experience pain 2 to 3 hours after a meal and at night. Two thirds of patients with duodenal ulcers will complain of pain that awakens them from sleep. The pain of gastric ulcer more commonly occurs with eating and is less likely to awaken the patient at night. A history of PUD, use of NSAIDs, over-the-counter antacids, or antisecretory drugs is suggestive of the diagnosis. Other signs and symptoms include nausea, bloating, weight loss, stool positive for occult blood, and anemia. Duodenal ulcer is about twice as common in men compared to women, but the incidence of gastric ulcer is similar in men and women. On average, gastric ulcer patients are older than duodenal ulcer patients, and the incidence is increasing in the elderly, perhaps because of increasing NSAID and aspirin.

Diagnosis

In the young patient with dyspepsia and/or epigastric pain, it may be appropriate to initiate empirical PPI therapy for PUD without confirmatory testing. In such cases, it is prudent to discuss with the patient the small possibility of an alternative diagnosis, including malignancy, even if symptoms improve with the initiation of therapy. All patients more than 45 years old with the above symptoms should have an upper endoscopy, and all patients, regardless of age, should have this study if any alarm symptoms (see Table 26-5) are present. A double-contrast upper GI X-ray study may be useful. Once an ulcer has been confirmed endoscopically or radiologically, obvious possible causes (Helicobacter, NSAIDs, gastrinoma, cancer) should always be considered. All gastric ulcers should be adequately biopsied, and any sites of gastritis should be biopsied to rule out H. pylori, and for histologic evaluation. Additional testing for H. pylori may be indicated. It is not unreasonable to test all peptic ulcer patients for H. pylori (Table 26-8) 63A baseline serum gastrin level is appropriate to rule out gastrinoma.

Table 26-8

Indications for diagnosis and treatment of Helicobacter pylori

Established

- Active peptic ulcer disease (gastric or duodenal ulcer)
- Confirmed history of peptic ulcer disease (not previously treated for H. pylori)
- Gastric mucosa-associated lymphoid tissue lymphoma (low grade)
- After endoscopic resection of early gastric cancer
- Uninvestigated dyspepsia (depending on H. pylori prevalence)

Controversial

- Nonulcer dyspepsia
- Gastroesophageal reflux disease
- Persons using NSAIDs
- Unexplained iron deficiency anemia
- Populations at higher risk for gastric cancer

Complications

The three most common complications of PUD, in decreasing order of frequency, are bleeding, perforation, and obstruction.51,52,64 Most peptic ulcer–related deaths in the United States are due to bleeding. Bleeding peptic ulcers are by far the most common cause of upper GI bleeding in patients admitted to hospital (Fig. 26-31).55 Patients with a bleeding peptic ulcer typically present with melena and/or hematemesis. Nasogastric aspiration is usually confirmatory of the upper GI bleeding. Abdominal pain is quite uncommon. Shock may be present, necessitating aggressive resuscitation and blood transfusion. Early endoscopy is important to diagnose the cause of the bleeding and to assess the need for hemostatic therapy.

Three-fourths of the patients who come to the hospital with bleeding peptic ulcer will stop bleeding if given acid suppression and nothing by mouth. However, one fourth will continue to bleed or will rebleed after an initial quiescent period, and virtually all the mortalities (and all the operations for bleeding) occur in this group. This group can be fairly well delineated based on clinical factors related to the magnitude of the hemorrhage, comorbidities, age, and endoscopic findings. Shock, hematemesis, transfusion requirement exceeding four units in 24 hours, and certain endoscopic stigmata (active bleeding or visible vessel) define this high-risk group. Two widely used risk stratification tools have proven useful in predicting rebleeding and death: the Blatchford and Rockall scores (Table 26-9).66 High-risk patients benefit from endoscopic therapy to stop the bleeding. The most common endoscopic hemostatic modalities used are injection with epinephrine, and electrocautery. In a case with exposed vessel, mechanical hemostasis using a clip is useful to control the bleeding.66 Persistent bleeding or rebleeding after endoscopic therapy is an indication for operation, although repeat endoscopic treatment has been successful in treating rebleeding. Elderly patients and patients with multiple comorbidities do not tolerate repeated episodes of hemodynamically significant hemorrhage, and may benefit from early elective operation after initially successful endoscopic treatment, especially if they have a high-risk ulcer.

Planned surgery under controlled circumstances often yields better outcomes than emergent surgery. Deep bleeding ulcers on the posterior duodenal bulb or lesser gastric curvature are high-risk lesions, because they often erode large arteries not amenable to nonoperative treatment, and early operation should be considered.

*Panel A shows the values used in the Blatchford risk-stratification score, which ranges from 0 to 23, with higher scores indicating higher risk. Panel B shows the Rockall score, with point values assigned for each of three clinical variables (age and the presence of shock and coexisting illnesses) and two endoscopic variables (diagnosis and stigmata of recent hemorrhage). The complete Rockall score ranges from 0 to 11, with higher scores indicating higher risk. Patients with a clinical Rockall score (Age + Shock + Coexisting illness) of 0 or a complete Rockall score of 2 or less are considered to be at low risk for rebleeding or death. Source: Reproduced with permission from Gralnek IM et al: Management of acute bleeding from peptic ulcer. N Engl J Med. 359:928, 2008. Copyright ©2008 Massachusetts Medical Society. All rights reserved.*
Perforated peptic ulcer usually presents as an acute abdomen. The patient can often give the exact time of onset of the excruciating abdominal pain. Initially, a chemical peritonitis develops from the gastric and/or duodenal secretions, but within hours a bacterial peritonitis supervenes. The patient is in obvious distress, and the abdominal examination shows peritoneal signs. Usually, marked involuntary guarding and rebound tenderness is evoked by a gentle examination. Upright chest X-ray shows free air in about 80% of patients (Fig. 26-32). Once the diagnosis has been made, the patient is given analgesia and antibiotics, resuscitated with isotonic fluid, and taken to the operating room. Fluid sequestration into the third space of the inflamed peritoneum can be impressive, so preoperative fluid resuscitation is mandatory. Sometimes, the perforation has sealed spontaneously by the time of presentation, and surgery can be avoided if the patient is doing well. Nonoperative management is appropriate only if there is objective evidence that the leak has sealed (i.e., radiologic contrast study), and in the absence of clinical peritonitis.

Gastric outlet obstruction occurs in no more than 5% of patients with PUD. It is usually due to duodenal or prepyloric ulcer disease, and may be acute (from inflammatory swelling and peristaltic dysfunction) or chronic (from cicatrix). Patients typically present with nonbilious vomiting and may have a profound hypokalemic hypochloremic metabolic alkalosis. Pain or discomfort is common. Weight loss may be prominent, depending on the duration of symptoms. A succussion splash may be audible with stethoscope placed in the epigastrium. Initial treatment is nasogastric suction, IV hydration and electrolyte repletion, and acid suppression. The diagnosis is confirmed by endoscopy. Most patients admitted to the hospital nowadays with obstructing ulcer disease require intervention, either balloon dilation or operation. Cancer must be ruled out because most patients who present with the symptoms of gastric outlet obstruction will have a pancreatic, gastric, or duodenal malignancy.

Medical Treatment of Peptic Ulcer Disease
PPIs are the mainstay of medical therapy for PUD, but high dose H₂RAs and sucralfate are also quite effective. Patients hospitalized for ulcer complications should receive PPI by continuous IV infusion, and, when discharged, should be considered for lifelong PPIs unless the definitive cause is eliminated or a definitive operation performed. Peptic ulcer patients should stop smoking and avoid alcohol and NSAIDs (including aspirin). Patients who require NSAIDs or aspirin to treat other medical conditions should always take concomitant PPIs or high dose H₂ receptor blockers. If *H. pylori* infection is documented, it should be treated with one of several acceptable regimens (Table 26-10). Infectious disease consultation may be helpful in the compliant, symptomatic patient with persistent *H. pylori* infection following treatment, or another regimen could be tried (e.g., quadruple therapy). If initial *H. pylori* testing is negative and ulcer symptoms persist, an empirical trial of anti-*H. pylori* therapy is reasonable since false-negative *H. pylori* tests are common. Generally, acid suppression can be stopped after 3 months if the ulcerogenic stimulus (usually *H. pylori*, NSAIDs, or aspirin) has been removed. However, long-term maintenance PPI therapy should be considered in all patients admitted to hospital with ulcer complications, all high-risk patients on NSAIDs or aspirin (the elderly or debilitated), and all patients with a history of recurrent ulcer or bleeding. Consideration should also be given to maintenance PPI therapy in refractory smokers with a history of peptic ulcer. Sucralfate acts locally on mucosal defects and is well tolerated, and occasionally is useful as a supplement to acid suppression.

**Surgical Treatment of Peptic Ulcer Disease**

The indications for surgery in PUD are bleeding, perforation, obstruction, and intractability or nonhealing. Gastric cancer must always be considered in patients with gastric ulcer or gastric outlet obstruction.

Today, most patients undergoing operation for PUD have simple oversewing of a bleeding ulcer or simple patch of a perforated ulcer. Simultaneous performance of vagotomy either truncal or highly selective is increasingly uncommon.

probably due to surgeon unfamiliarity with the procedure and reliance on postoperative PPIs to decrease acid secretion.

Unfortunately, the data from many excellent randomized clinical trials evaluating elective operation for peptic ulcer over the last several decades may be irrelevant to most patients presenting for ulcer surgery today. The large majority of these excellent studies were done in the pre-PPI, pre- Helicobacter, pre-NSAID era, and focused on elective operation for intractable disease, an unusual indication for operation nowadays. Thus, today’s surgeon should take great care in applying this literature to inform surgical decision making.

Traditionally, the vast majority of peptic ulcers were treated by a variant of one of the three basic operations: parietal cell vagotomy also called highly selective vagotomy or proximal gastric vagotomy (HSV), vagotomy and drainage (V+D), and vagotomy and distal gastrectomy. Recurrence rates were lowest but morbidity highest with the latter procedure, while the opposite was true for HSV (Table 26-11).

HSV severs the vagal nerve supply to the proximal two thirds of the stomach, where essentially all the parietal cells are located, and preserves the vagal innervation to the antrum and pylorus, and the remaining abdominal viscera (Fig. 26-33). Thus, the operation decreases total gastric acid secretion by about 75%, and GI side effects are rare. Elective HSV has largely been supplanted by long-term PPI treatment, but the operation, which has a learning curve, may still be useful in the patient (elective or emergent) who is noncompliant with, intolerant of, or cannot afford medical treatment. Historically, HSV has not performed particularly well for type II (gastric and duodenal) and III (prepyloric) gastric ulcer, perhaps because of hypergastrinemia caused by gastric outlet obstruction and persistent antral stasis. The Taylor procedure consists of a posterior truncal vagotomy and anterior seromyotomy (but anterior HSV is probably equivalent), and is an attractive and simple alternative to HSV with similar results.

Truncal vagotomy and pyloroplasty, and truncal vagotomy and gastrojejunostomy are the paradigmatic vagotomy and drainage procedures. HSV may be substituted for truncal vagotomy. The advantage of V + D is that it can be performed safely and quickly by the experienced surgeon. The main disadvantages are the side effect profile (10% of patients have significant dumping and/or diarrhea). During truncal vagotomy (Fig. 26-34), care must be taken not to perforate the esophagus, a potentially lethal complication. Intraoperative frozen section confirmation of at least two vagal trunks is prudent; additional vagal trunks are common. Unlike HSV, V + D is widely accepted as a successful definitive operation for complicated PUD. It has been described as a useful part of the operative treatment for bleeding duodenal and gastric ulcer, perforated duodenal and gastric ulcer, and obstructing duodenal and gastric (type II and III) ulcer. When applied to gastric ulcer, the ulcer should be excised or biopsied.

Truncal vagotomy denervates the antpyloric mechanism, and therefore, some sort of procedure is necessary to ablate or bypass the pylorus. Gastrojejunostomy is a good choice in patients with gastric outlet obstruction or a severely diseased proximal duodenum. The anastomosis is done between the proximal jejunum and the most dependent portion of the greater gastric curvature, in either an antecolic or retrocolic fashion (Fig. 26-35). Marginal ulceration is a potential complication. Pyloroplasty is useful in patients who require a pyloroduodenotomy to deal with the ulcer complication (e.g., posterior bleeding duodenal ulcer), in those with limited or focal scarring in the pyloric region, or when gastrojejunostomy is technically difficult. The most commonly performed
pyloroplasty is the Heineke-Mikulicz type (Fig. 26-36). Other occasionally useful techniques include the Finney (Fig. 26-37) and the Jaboulay pyloroplasties (Fig. 26-38). These more extensive pyloroplasty techniques may make subsequent distal gastric resection more difficult and/or hazardous.

Although vagotomy and antrectomy (V + A) is associated with a very low ulcer recurrence rate and is applicable to many patients with complicated PUD (e.g., bleeding duodenal and gastric ulcer, obstructing peptic ulcer, nonhealing gastric ulcer, and recurrent ulcer), V + A has a higher operative mortality risk (compared with HSV or V + D), and is irreversible. Following antrectomy, GI continuity may be reestablished with a Billroth I gastroduodenostomy (Fig. 26-39) or a Billroth II loop gastrojejunostomy (Fig. 26-40). Since antrectomy routinely leaves a 60% to 70% gastric remnant, routine reconstruction as a Roux-en-Y gastrojejunostomy should be avoided (Fig. 26-41).

Although the Roux-en-Y operation is an excellent procedure for keeping duodenal contents out of the stomach and esophagus, in the presence of a large gastric remnant, this reconstruction will predispose to marginal ulceration and/or gastric stasis. V + A should be avoided in hemodynamically unstable patients, and in patients with extensive inflammation and/or scarring of the proximal duodenum, because secure anastomosis (Billroth I) or duodenal closure (Billroth II) may be difficult.

Distal gastrectomy without vagotomy (usually about a 50% gastrectomy to include the ulcer) has traditionally been the procedure of choice for type I gastric ulcer. The addition of vagotomy should be considered for type II and III gastric ulcers (because the pathophysiology is more analogous to duodenal ulcer), or if the patient is believed to be at increased risk for recurrent ulcer, or perhaps even if Billroth II reconstruction is contemplated (to decrease the chance of marginal ulcer). Subtotal gastrectomy (75% distal gastrectomy) without vagotomy is rarely used to treat PUD today, although it was the most popular ulcer operation at the middle of the last century.

Pylorus preserving gastrectomy (PPG) was first reported as a surgical option for gastric ulcer which could minimize both dumping and duodenogastric reflux. Though not widely adopted for this indication, in some centers PPG is considered a good minimally invasive surgical option for early gastric cancer.

Choice of Operation for Peptic Ulcer. The choice of operation for the individual patient with PUD depends on a variety of factors, including the type of ulcer (duodenal, gastric, recurrent, or marginal), the indication for operation, and the condition of the patient, among others. Other important considerations are intrabdominal factors (duodenal scarring/inflammation, adhesions, or difficult exposure), the ulcer diathesis status of the patient, the surgeon’s experience and personal preference, whether H. pylori infection is present, the need for NSAID therapy, previous treatment, and the likelihood of future compliance with treatment. Table 26-12 shows the surgical options for managing various aspects of PUD. In general, resective procedures have a lower ulcer recurrence rate, but a higher operative morbidity and mortality rate (see Table 26-11) compared to nonresective ulcer operations. Because ulcer recurrence often is related to H. pylori infection, eradication of H. pylori infection should be considered in all patients with PUD who are surgical candidates.
and/or NSAIDs, it is usually managed adequately without reoperation. Thus, gastric resection to minimize recurrence in duodenal ulcer disease is often not justified today; resection for gastric ulcer remains the standard because of the risk of cancer. Clearly, the modern trend in peptic ulcer operation could be described as “less is more.” Vagotomy as a component of emergency ulcer operation is increasingly uncommon.

Bleeding Peptic Ulcer

Bleeding is the most common cause of ulcer-related death, but most patients admitted to hospital with bleeding gastric or duodenal ulcer today will not require an operation. In many hospitals, operation for ulcer perforation is much more common than operation for bleeding ulcer. The success of endoscopic treatment and medical therapy in treating and preventing bleeding PUD has resulted in the selection of a small subgroup of high-risk patients for today’s surgeon. It is likely that patients currently coming to operation for bleeding PUD are at higher risk for a poor outcome than ever before. The surgical options for treating bleeding PUD include suture ligation of the bleeder; suture ligation and definitive nonresective ulcer operation (HSV or V + D); and gastric resection (usually, including vagotomy and ulcer excision). Gastric ulcer requires biopsy if not resected.

The management of bleeding peptic ulcer is summarized in the algorithm provided in Fig. 26-42. All patients admitted to hospital with bleeding peptic ulcer should be adequately resuscitated and started on continuous IV PPI. Seventy-five percent of patients will stop bleeding with these measures alone, but 25% will continue to bleed or will rebleed in hospital. It is important to identify this high-risk group early with clinical
and endoscopic parameters because, essentially, all the deaths from bleeding ulcer occur in this group. Surgical consultation is mandatory, and endoscopic hemostatic therapy (cautery, epinephrine injection, clipping) is indicated and usually successful in these high-risk patients.\textsuperscript{73,74} Indications for operation include massive hemorrhage unresponsive to endoscopic control, and transfusion requirement of more than four to six units of blood, despite attempts at endoscopic control. Lack of availability of a therapeutic endoscopist, recurrent hemorrhage after one or more attempts at endoscopic control, lack of availability of blood for transfusion, repeat hospitalization for bleeding ulcer, and concurrent indications for surgery such as perforation or obstruction, are also indications for surgery. Patients with massive bleeding from high-risk lesions (e.g., posterior duodenal ulcer with erosion of gastroduodenal artery, or lesser curvature gastric ulcer with erosion of left gastric artery or branch) should be considered for early operation. Early operation should also be considered in patients more than 60 years of age, those presenting in shock, those requiring more than four units of blood in 24 hours or eight units of blood in 48 hours, those with rebleeding, and those with ulcers $>2$ cm in diameter. The mortality rate for surgery for bleeding peptic ulcer is around 20%. Angiography and embolization may be useful in some patients.

**Operation for Bleeding Peptic Ulcer (Fig. 26-43)**

The two operations most commonly used for bleeding duodenal ulcer are oversewing of the ulcer usually without vagotomy,\textsuperscript{70} or $V + A$. Oversewing alone results in a higher rebleeding rate.
but a lower operative mortality rate. When the mortality for reoperation for rebleeding is considered, the overall mortality is probably comparable for the two approaches. Patients who are in shock or medically unstable should not have gastric resection.

An initial pyloromyotomy incision allows access to the bleeding posterior duodenal ulcer, and an expeditious Kocher maneuver allows the surgeon to control the hemorrhage with the left hand if necessary. Heavy suture material on a stout needle is used to place figure-of-eight sutures or a U-stitch to secure the bleeding vessel at the base of the posterior duodenal ulcer. Multiple sutures are usually necessary. Once the surgeon is unequivocally convinced that hemostasis is secure, a pyloroplasty can be performed. If the patient is stable, vagotomy may be considered if the surgeon is experienced and the vagotomy straightforward. If the patient is not a high operative risk and V + A is selected, smaller duodenal ulcers are resected with the specimen; larger bleeding duodenal ulcers must often be left behind in the duodenal stump. In this situation, suture hemostasis must be attained and a secure duodenal closure accomplished. The anterior wall of the open duodenum can be sutured to either the proximal or distal lip of the posterior ulcer once the bleeding vessel has been sutured. The duodenal closure can be buttressed with omentum and the duodenum should be

decompressed, either with a lateral duodenostomy or retrograde tube via the proximal jejunum or nasogastric tube secured with tip well into afferent limb. Right upper quadrant closed suction peritoneal drainage is important. Use of a feeding jejunostomy is also considered. A Billroth II anastomosis reestablishes gastrointestinal continuity.

The initial management of bleeding gastric ulcers and the indications for operation are similar to those for bleeding duodenal ulcer. These lesions tend to occur in older and/or medically complicated patients, and this fact may increase the operative risk. However, experience shows that planned surgery in a resuscitated patient results in a better operative survival rate than emergent operation in a patient who has rebled and is in shock. Distal gastric resection to include the bleeding ulcer is the procedure of choice for bleeding gastric ulcer. Second best is V + D with oversewing and biopsy of the ulcer to rule out cancer. Overswing of the bleeder followed by long-term acid suppression is a reasonable alternative in high-risk or unstable patients.

**Perforated Peptic Ulcer (Fig. 26-44)**

Perforation is the second most common complication of peptic ulcer but nowadays a more common indication for operation than bleeding. As with bleeding ulcer, NSAID and/or aspirin use have been inextricably linked with perforated PUD, especially in the elderly population. Surgery is almost always indicated for ulcer perforation, although occasionally nonsurgical treatment can be used in the stable patient without peritonitis in whom radiologic studies document a sealed perforation. Patients with acute perforation and GI blood loss (either chronic or acute) should be suspected of having a second ulcer or a GI cancer.

The options for surgical treatment of perforated duodenal ulcer are simple patch closure, patch closure and HSV, or patch closure and V + D. Simple patch closure, currently the most commonly performed operation for perforated peptic ulcer, should be done in patients with hemodynamic instability and/or exudative peritonitis signifying a perforation >24 hours old. In stable patients without longstanding perforation, the addition of HSV may be considered. However, in the United States and Western Europe, there is clearly a trend away from definitive operation for perforated duodenal ulcer, probably because of the ready availability of PPI, and surgeon unfamiliarity with definitive operation in this setting.

In the stable patient without multiple operative risk factors, perforated gastric ulcers are best treated by distal gastric resection. Vagotomy is usually added for type II and III gastric ulcers. Patch closure with biopsy; or local excision and closure; or biopsy, closure, truncal vagotomy, and drainage are alternative operations in the unstable or high-risk patient, or in the patient with a perforation in an inopportune location. All perforated gastric ulcers, even those in the prepyloric position, should be biopsied if they are not removed at surgery.

**Obstructing Peptic Ulcer**

Acute ulcers associated with obstruction due to edema and/or motor dysfunction may respond to intensive antisecretory therapy and nasogastric suction. But most patients with significant obstruction from chronic ulceration will require some sort of more substantial intervention. Endoscopic balloon dilation can often transiently improve obstructive symptoms, but many of these patients ultimately fail and come to operation.

<sup>a</sup>Unless the patient is in shock or moribund, a definitive procedure should be considered.
<sup>b</sup>Operation of choice in low-risk patient.

GI = gastrojejunostomy; HSV = highly selective vagotomy; V + A = vagotomy and antrectomy; V + D = vagotomy and drainage.

---
The standard operation for obstructing PUD is vagotomy and antrectomy. Alternatively vagotomy and gastrojejunostomy should be considered if a difficult duodenal stump is anticipated with resection. HSV and gastrojejunostomy may be comparable to V+A for obstructing ulcer disease, and sometimes has appeal because it can be done laparoscopically, and because it does not complicate future resection, if needed. However, potentially curable gastric or duodenal cancers can be missed with this approach.

Intractable or Nonhealing Peptic Ulcer

Intractability should be an unusual indication for peptic ulcer operation nowadays. The patient referred for surgical evaluation because of intractable PUD should raise red flags for the surgeon: Maybe the patient has a missed cancer; maybe the patient is noncompliant (not taking prescribed PPI, still taking NSAIDs, still smoking); maybe the patient has *Helicobacter* despite the presence of a negative test or previous treatment. Because acid secretion can be totally blocked and *H. pylori* eradicated with modern medication, the question remains: “Why does the patient have a persistent ulcer diathesis?” The surgeon should review the differential diagnosis of nonhealing ulcer before any consideration of operative treatment (Table 26-13).

Surgical treatment should be considered in patients with nonhealing or intractable PUD who have multiple recurrences, large ulcers (>2 cm), complications (obstruction, perforation, or...

hemorrhage), or suspected malignancy. Definitive operation, particularly gastric resection, should be considered most cautiously in the thin or marginally nourished individual.

It is important that the surgeon not fall into the trap of performing a large, irreversible operation on these patients, based on the unproven theory that if all other methods have failed to heal the ulcer, a large operation is required. Although there is a large quantity of very good data in the surgical literature suggesting that the large majority of patients do well after the larger elective ulcer operations, these data may not be particularly relevant to the modern patient.

Candidates for ulcer operation today are different than those of 30 to 50 years ago. One might argue that current medical care has healed the minor ulcers, and that patients presenting with true intractability or nonhealing will be more difficult to treat and are likely to have chronic problems after a major ulcer operation.

If surgery is necessary, a lesser operation may be preferable. It is prudent to avoid truncal vagotomy and/or distal gastrectomy as the initial elective operation for intractable peptic ulcer in the thin or asthenic patient. Alternatives for intractable duodenal ulcer include HSV with or without gastrojejunostomy (reversible drainage operation). In patients with nonhealing gastric ulcer, wedge resection with HSV should be considered in thin or frail patients. Otherwise, distal gastrectomy (to include the ulcer) is recommended. It is unnecessary to add a vagotomy in patients with type I or type IV (juxta-esophageal) gastric ulcers because they are usually associated with acid hyposecretion. Type IV gastric ulcers may be difficult to resect as part of a distal gastrectomy, and a variety of surgical techniques have been described to treat these more proximal lesions (Fig. 26-45).

Zollinger-Ellison Syndrome

ZES is caused by the uncontrolled secretion of abnormal amounts of gastrin by a duodenal or pancreatic neuroendocrine tumor (i.e., gastrinoma). Most cases (80%) are sporadic, but 20% are inherited. The inherited or familial form of gastrinoma is associated with multiple endocrine neoplasia type I (MEN I), which consists of parathyroid, pituitary, and pancreatic (or duodenal) tumors. Gastrinoma is the most common pancreatic tumor in patients with MEN I. Patients with MEN I usually have multiple gastrinoma tumors, and surgical cure is less common; sporadic gastrinomas are more often solitary and are more often amenable to surgical cure. Currently, about 50% to 60% of gastrinomas are malignant, with lymph node, liver, or other distant metastases at operation. Five-year survival in patients presenting with metastatic disease is approximately 40%. The larger the primary gastrinoma, the higher the likelihood of metastatic disease. More than 90% of patients with sporadically, completely resected gastrinoma will be cured.

The most common symptoms of ZES are epigastric pain, GERD, and diarrhea. More than 90% of patients with gastrinoma have peptic ulcer. Most ulcers are in the typical location (proximal duodenum), but atypical ulcer location (distal duodenum, jejunum, or multiple ulcers) should prompt an evaluation for gastrinoma. Gastrinoma also should be considered in

the differential diagnosis of recurrent or refractory peptic ulcer, secretory diarrhea, gastric rugal hypertrophy, esophagitis with stricture, bleeding or perforated ulcer, familial ulcer, peptic ulcer with hypercalcemia, and gastric carcinoid. The majority of patients with ZES have been symptomatic for several years before definitive diagnosis and, in general, patients with ZES and MEN1 are diagnosed in their 20s and 30s, while those with sporadic ZES more typically are diagnosed in their 40s and 50s.

ZES is an important part of the differential diagnosis of hypergastrinemia (Fig. 26-46). All patients with gastrinoma have an elevated gastrin level, and hypergastrinemia in the presence of elevated BAO strongly suggests gastrinoma. Patients with gastrinoma usually have a BAO >15 mEq/h or >5 mEq/h if they have had a previous procedure for peptic ulcer. Acid-suppressing medications should be held for several days before gastrin measurement, because acid suppression may falsely elevate gastrin levels. Causes of hypergastrinemia can be divided into those associated with hyperacidity and those associated with hypoacidity (see Fig. 26-46). The diagnosis of ZES is confirmed by the secretin stimulation test. An IV bolus of secretin (2 U/kg) is given and gastrin levels are checked before and after injection. An increase in serum gastrin of 200 pg/mL or greater suggests the presence of gastrinoma. Patients with gastrinoma should have serum calcium and parathyroid hormone levels determined to rule out MEN1 and, if present, parathyroidectomy should be considered before resection of gastrinoma.

About 80% of primary tumors are found in the gastrinoma triangle (Fig. 26-47), and many tumors are small (<1 cm), making preoperative localization difficult. Transabdominal ultrasound is quite specific, but not very sensitive. CT will detect most lesions >2 cm in size and MRI is comparable. EUS is more sensitive than these other noninvasive imaging tests, but it still misses many of the smaller lesions, and may confuse normal lymph nodes for gastrinomas. Currently, the preoperative imaging study of choice for gastrinoma is somatostatin receptor scintigraphy (the octreotide scan). When the pretest probability of gastrinoma is high, the sensitivity and specificity of this modality approach 100%. Gastrinoma cells contain type II somatostatin
receptors that bind the indium-labeled somatostatin analogue (octreotide) with high affinity, making imaging with a gamma camera possible (Fig. 26-48). Currently, angiographic localization studies are infrequently performed for gastrinoma. Both diagnostic angiography and transhepatic selective venous sampling of the portal system have been supplanted by selective arterial secretin infusion, which helps to localize the tumor as inside or outside the gastrinoma triangle.

In this test, an arterial catheter is selectively placed in a named vessel supplying the pancreas (e.g., gastroduodenal or splenic), and a venous catheter is placed in a hepatic vein. Secretin is injected into the visceral artery and gastrin is sampled in the hepatic vein. A significant elevation in hepatic venous gastrin indicates that the tumor is supplied by the injected artery. This test should be performed if pancreaticoduodenectomy is contemplated. Probably the most important means of locating gastrinomas is intraoperative exploration.

All patients with sporadic (nonfamilial) gastrinoma should be considered for surgical resection and possible cure. The lesions should be located in 90% of patients, and the large majority is cured by extirpation of the gastrinoma(s). A thorough intraoperative exploration of the gastrinoma triangle and pancreas is essential, but other sites (i.e., liver, stomach, small bowel, mesentery, and pelvis) should be evaluated as part of a thorough intra-abdominal evaluation to find the primary tumor, which is usually solitary and often in the duodenal wall. The duodenum and pancreas should be extensively mobilized and intraoperative ultrasound should be used. Intraoperative EGD with transillumination may be considered. If the tumor can not be located, generous longitudinal duodenotomy with inspection and palpation of the duodenal wall is performed. Lymph nodes from the portal, peripancreatic, and celiac drainage basins should be sampled. Ablation or resection of hepatic metastases should be considered.

The management of gastrinoma in patients with MEN I is controversial because the patients are often not cured by operation, and the tumors tend to be small and multiple. If the tumor can be imaged preoperatively, operation by an experienced gastrinoma surgeon is reasonable.

Acid hypersecretion in patients with gastrinoma can always be managed with high-dose PPIs. Highly selective vagotomy may make management easier in some patients and should be considered in those with surgically untreatable or unresectable gastrinoma. Gastrectomy for ZES is no longer indicated.

**GASTRITIS AND STRESS ULCER**

**Pathogenesis and Prevention**

Gastritis is mucosal inflammation. The gross endoscopic diagnosis of gastritis correlates poorly with histologic findings, and is thus relatively useless as a diagnosis without confirmatory biopsy. Additionally, there is poor correlation between symptoms and histologic gastritis. The most common cause of gastritis is *H. pylori*. Other causes of gastritis include alcohol, NSAIDs, Crohn’s disease, tuberculosis, and bile reflux (primary or secondary). These agents cause injury by a variety of different mechanisms. In general, the infectious and inflammatory causes result in immune cell infiltration and cytokine production which damage mucosal cells. The chemical agents (alcohol, aspirin, and bile) generally work to disrupt the mucosal barrier, allowing mucosal damage by back diffusion of luminal hydrogen ions.
Stress gastritis is a peculiar entity that has all but disappeared from the clinical (if not endoscopic) lexicon, largely due to better critical care and acid suppression or cytoprotective agents (e.g., sucralfate) in the intensive care unit (ICU). Stress gastritis and stress ulcer are probably due to inadequate gastric mucosal blood flow during periods of intense physiologic stress. Adequate mucosal blood flow is important to maintain the mucosal barrier, and to buffer any back-diffused hydrogen ions. When blood flow is inadequate, these processes fail and mucosal breakdown occurs. Modern intensive care, with emphasis on adequate tissue perfusion and oxygenation, has undoubtedly decreased the severity of gastric mucosal injury seen in the ICU today. Although it is still common to see small mucosal erosions when performing upper endoscopy in the ICU, it is rare for these lesions to coalesce into the larger bleeding erosions that plagued the ICU patient 30 to 50 years ago. The rationale for routine acid suppression in the ICU, supported by excellent data from clinical trials and the laboratory, is that less mucosal injury will be caused in the potentially weakened gastric mucosa if there is less luminal acid.

**MALIGNANT NEOPLASMS OF THE STOMACH**

The three most common primary malignant gastric neoplasms are adenocarcinoma (95%), lymphoma (4%), and malignant GIST (1%) (Table 26-14). Other rare primary malignancies include carcinoid, angiosarcoma, carcinosarcoma, and squamous cell carcinoma. Occasionally the stomach is the site of hematogenous metastasis from other sites (e.g., melanoma or breast). More commonly, malignant tumors from adjacent organs invade the stomach by direct extension (e.g., colon or pancreas) or by peritoneal seeding (e.g., ovary).

### Adenocarcinoma

**Epidemiology.** Globally, gastric cancer is the fourth most common cancer type and the second leading cause of cancer death. Over the past several decades, there has been a dramatic decrease in the gastric cancer incidence and death rate in most Western industrialized countries (Fig. 26-49). This decrease has been largely in the so-called intestinal form rather than in the diffuse form of gastric cancer. In Asia and Eastern Europe, gastric cancer remains a leading cause of cancer death. In 2012 in the United States, there were approximately 21,320 new cases of stomach cancer (13,020 in men and 8300 in women), and 10,540 deaths from this disease (6190 men and 4350 women). The estimated 5-year survival rate is 27%, up from about 15% in 1975.

In general, gastric cancer is a disease of the elderly, and it is twice as common in blacks as in whites. In younger patients, tumors are more often of the diffuse variety and tend to be large, aggressive, and more poorly differentiated, sometimes infiltrating the entire stomach (linitis plastic). Gastric cancer has a higher incidence in groups of lower socioeconomic status.

**Etiology.** Gastric cancer is more common in patients with pernicious anemia, blood group A, or a family history of gastric cancer. When patients migrate from a high-incidence region to a low-incidence region, the risk of gastric cancer decreases in the subsequent generations born in the new region. This strongly suggests an environmental influence on the development of gastric cancer. Environmental factors appear to be more related etiologically to the intestinal form of gastric cancer than the more aggressive diffuse form. The commonly accepted risk factors for gastric cancer are listed in Table 26-15.

**Diet and Drugs.** Typically, a starchy diet high in pickled, salted, or smoked food is found in many regions of high gastric cancer risk. Dietary nitrates have been impugned as a possible cause of gastric cancer. Gastric bacteria (more common in the achlorhydric stomach of patients with atrophic gastritis, a risk factor for gastric cancer) convert nitrate into nitrite, a proven carcinogen. A diet high in fresh fruits and vegetables and rich in vitamin C and E has been shown to decrease the population’s risk of gastric cancer. The reduced consumption of nitrate-rich preserved foods seen with the growth of refrigeration has been suggested as a cause of the dramatic decrease in gastric cancer seen in North America and Western Europe over the last century. Tobacco use probably increases the risk of stomach cancer, and alcohol use probably has no effect. Regular aspirin use may be protective.

### Helicobacter pylori

The risk of gastric cancer in patients with chronic *H. pylori* infection is increased about threefold. Compared to uninfected patients, patients with a history of gastric ulcer are more likely to develop gastric cancer (incidence ratio 1.8, 95% confidence interval 1.6–2.0), and patients with a history of duodenal ulcer are at decreased risk for gastric cancer (incidence ratio 0.6, 95% confidence interval 0.4–0.7). As diagrammed in Fig. 26-50, this may be due to the fact that some patients develop antral-predominant disease (predisposing to duodenal ulcer and somehow protecting against

</table>

gastric cancer), while other patients develop corpus-predominant gastritis, resulting in hypochlorhydria and somehow predisposing to gastric ulcer and gastric cancer.

The theoretical sequence for development of gastric adenocarcinoma is diagrammed in Fig. 26-51. Recently, it has been demonstrated that bone marrow-derived stem cells play a key role in the pathogenesis of gastric adenocarcinoma in patients with chronic *H. pylori* infection. However, it must be recognized that gastric adenocarcinoma is a multifactorial disease. Not all patients with gastric cancer have *H. pylori*, and there are some geographic areas with a high prevalence of chronic *H. pylori* infection and a low prevalence of gastric cancer (the “African enigma”).

Finally, *H. pylori*-infected patients seem to be at decreased risk for the development of adenocarcinoma of the distal esophagus and cardia region. Perhaps the corporeal gastritis decreases acid secretion, creating a less damaging refluxate and thus reducing the risk for Barrett’s esophagus, the precursor lesion for these tumors.

**Epstein-Barr Virus** About 10% of gastric adenocarcinomas carry the EBV virus. Recently it has been suggested that EBV infection is a rather late step in gastric carcinogenesis, since EBV transcripts are present in cancer cells but not in the metaplastic cells of precursor epithelium.

**Genetic Factors** A variety of genetic abnormalities have been described in gastric cancer (Table 26-16). Most gastric cancers are aneuploid. The most common genetic abnormalities in sporadic gastric cancer affect the *p53* and *COX-2* genes. Over two thirds of gastric cancers have deletion or suppression of the *p53* gene, and approximately the same proportion have overexpression of *COX-2*. In the colon, tumors with upregulation of this gene have suppressed apoptosis, more angiogenesis, and higher metastatic potential.

Gastric tumors that overexpress *COX-2* are more aggressive. Recently, a germline mutation in the *CDH1* gene encoding E-cadherin was shown to be associated with hereditary diffuse gastric cancer. Prophylactic total gastrectomy should be considered in patients with these mutations.

Recently the role of microRNA abnormalities in gastric cancer have received attention. These are small short sequence molecules (18 to 25 nucleotides) which inhibit the translation or promote the degradation of messenger RNA with complementary sequences. MicroRNAs are important regulators of gene expression, and abnormalities in microRNA have been identified in gastric cancer which effect the cell cycle, apoptosis, and cellular invasiveness and/or metastatic potential. It is likely

microRNA will have increasing diagnostic, therapeutic, and prognostic significance in gastric cancer as well as other tumors.

**Premalignant Conditions of the Stomach** Figure 26-52 shows the prevalence of some premalignant conditions associated with the development of early gastric cancer in a series of 1900 cases from Tokyo. By far the most common precancerous lesion is atrophic gastritis. There is a growing appreciation of the important influence of the chronic inflammatory milieu on the genome of mucosal cells. Chronic inflammation leads to both genetic and epigenetic changes in mucosal cells which in the stomach leads to the development of gastritis associated cancer.90

**Polyps** Benign gastric polyps are classified as neoplastic (adenoma and fundic gland polyps) or nonneoplastic (hyperplastic polyp, inflammatory polyp, hamartomatous polyp).90 In general, inflammatory and hamartomatous polyps have little or no malignant potential. Fundic gland polyps, commonly seen in patients on long term proton pump inhibitor therapy, are not premalignant but in patients with familial adenomatous polyposis, dysplasia in these lesions is not uncommon. Hyperplastic polyps usually occur in the setting of chronic inflammation. Large hyperplastic polyps (>2cm) may harbor dysplasia or carcinoma in situ, and gastric cancer may develop remote from the hyperplastic polyp in an area of associated chronic inflammation. Gastric adenomas are premalignant, similar to colon adenomas. Patients with familial adenomatous polyposis (FAP) have a high prevalence of gastric adenomatous polyps (about 50%), and are

10 times more likely to develop adenocarcinoma of the stomach than the general population. Screening EGD is indicated in these families. Patients with hereditary nonpolyposis colorectal cancer may also be at risk for gastric cancer.

Gastric polyps greater than 1 cm should be removed to confirm the diagnosis and to eliminate any risk of malignant degeneration. Patients with gastric adenomatous polyps and FAP should have periodic upper endoscopy, which may also be considered in selected patients with hyperplastic polyps and chronic gastric inflammation.

**Atrophic Gastritis** Chronic atrophic gastritis (Fig. 26-53) is by far the most common precursor for gastric cancer, particularly the intestinal subtype (see Fig. 26-52). The prevalence of atrophic gastritis is higher in older age groups, but it is also common in younger people in areas with a high incidence of gastric cancer. In many patients, it is likely that *H. pylori* is involved in the pathogenesis of atrophic gastritis. Correa described three distinct patterns of chronic atrophic gastritis: autoimmune (involves the acid-secreting proximal stomach), hypersecretory (involving the distal stomach), and environmental (involving multiple random areas at the junction of the oxyntic and antral mucosa).84

**Intestinal Metaplasia** Gastric carcinoma often occurs in an area of intestinal metaplasia. Furthermore, an individual’s risk of gastric cancer is proportional to the extent of intestinal metaplasia of the gastric mucosa. These observations strongly suggest that intestinal metaplasia is a precursor lesion to gastric cancer. There are different pathologic subtypes of intestinal metaplasia in the stomach, based upon the histologic and biochemical characteristics of the changed mucosal glands. In the complete type of intestinal metaplasia, the glands are completely lined with goblet cells and intestinal absorptive cells (Fig. 26-54). These cells are indistinguishable histologically and biochemically from their small bowel counterparts, and are not seen in the normal stomach. There is evidence that eradication of *H. pylori* infection leads to significant regression of intestinal metaplasia and improvement in atrophic gastritis. Therefore, treatment of *H. pylori* infection is a reasonable recommendation for patients with these pathologic diagnoses and *H. pylori* infection.

Figure 26-53. Chronic atrophic gastritis. (Reproduced with permission from http://www.epathologies.)
Benign Gastric Ulcer Although once considered a premalignant condition, it is likely that the older literature was confounded by mistakenly labeling inadequately biopsied ulcers and healing ulcers as “benign,” when, in fact, they were malignant to begin with. It is now generally recognized that all gastric ulcers are cancer until proven otherwise with adequate biopsy and follow-up. Even today, carcinomas are occasionally found when adequately biopsied “benign” ulcers are resected for nonhealing. It is more than likely that the factors previously discussed are more significant etiologically in the development of gastric cancer than the history of a benign gastric ulcer.

Gastric Remnant Cancer It has long been recognized that stomach cancer can develop in the gastric remnant, usually years following distal gastrectomy for PUD. The risk is controversial, but the phenomenon is real. Most tumors develop >10 years following the initial operation, and they usually arise in an area of chronic gastritis, metaplasia, and dysplasia. This is often near the stoma, but many of these tumors are quite large at presentation, and are equally divided between intestinal and diffuse subtypes. Most cases have been reported following Billroth II gastroenterostomy, but there also have been cases following Billroth I gastroduodenostomy. Whether simple loop gastrojejunostomy increases a patient’s risk of gastric cancer, and whether a Roux-en-Y anastomosis following gastric resection lowers their risk of gastric cancer is unknown. Stage for stage, the prognosis for gastric stump cancer is similar to proximal gastric cancer.

Other Premalignant States A mutated E-cadherin gene is associated with hereditary diffuse gastric cancer. Prophylactic total gastrectomy should be considered. Obviously, a myriad of genetic and environmental factors will affect members of the same family, and up to 10% of gastric cancer cases appear to be familial without a clear-cut genetic diagnosis. First-degree relatives of patients with gastric cancer have a two- to threefold increased risk of developing the disease. Patients with hereditary nonpolyposis colorectal cancer have a 10% risk of developing gastric cancer, predominantly the intestinal subtype. The mucous cell hyperplasia of Menetrier’s disease is generally considered to carry a 5% to 10% risk of adenocarcinoma. Periodic surveillance EGD is prudent in all the above conditions. The glandular hyperplasia associated with gastrinoma is not premalignant, but ECL hyperplasia and/or carcinoid tumors can occur.

Pathology

Dysplasia It is generally accepted that gastric dysplasia is the universal precursor to gastric adenocarcinoma. Patients with severe dysplasia should be considered for gastric resection if the abnormality is widespread or multifocal, or EMR if the severe dysplasia is localized. Patients with mild dysplasia should be followed with endoscopic biopsy surveillance, and Helicobacter eradication.

Early Gastric Cancer Early gastric cancer is defined as adenocarcinoma limited to the mucosa and submucosa of the stomach, regardless of lymph node status. The entity is common in the Orient, where gastric cancer is a common cause of cancer death, and where aggressive surveillance programs have therefore been established. Approximately 10% of patients with early gastric cancer will have lymph node metastases. There are several types and subtypes of early gastric cancer (Table 26-17 and Fig. 26-55). Approximately 70% of early gastric cancers are well differentiated, and 30% are poorly differentiated. The overall cure rate with adequate gastric resection and lymphadenectomy is 95%. In some Japanese centers, 50% of the gastric cancers treated are early gastric cancer. In the United States, less than 20% of resected gastric adenocarcinomas are early gastric cancer. Small intramucosal lesions can be treated with EMR.

Gross Morphology and Histologic Subtypes There are four gross forms of gastric cancer: polypoid, fungating, ulcerative, and scirrrous. In the first two, the bulk of the tumor mass is intraluminal. Polypoid tumors are not ulcerated; fungating tumors are elevated intraluminally, but also ulcerated. In the latter two gross subtypes, the bulk of the tumor mass is in the wall of the stomach. Ulcerative tumors are self-descriptive; scirrrous tumors infiltrate the entire thickness of the stomach and cover a very large surface area. Scirrrous tumors (limitis plastica) have a particularly poor prognosis, and commonly involve the entire stomach. Although these latter lesions may be technically resectable with total gastrectomy, it is common for both the esophageal and duodenal margins of resection to show microscopic evidence of tumor infiltration, and death from recurrent disease within 6 months is common. Palliative chemotherapy may prolong median survival.

*Tumors with less than 3-mm elevation are usually classified as –IIa, with more elevated tumors being classified as 0-I.
The location of the primary tumor in the stomach is important in planning the operation. Several decades ago, the large majority of gastric cancers were in the distal stomach. Recently, there has been a proximal migration of tumors, so that currently, the distribution is closer to 40% distal, 30% middle, and 30% proximal.

**Histology** The most important prognostic indicators in gastric cancer are both histologic: lymph node involvement and depth of tumor invasion. Tumor grade (degree of differentiation: well, moderately, or poorly) is also important prognostically.

There are several histologic classifications of gastric cancer. The World Health Organization recognizes several histologic types (Table 26-18). The Japanese classification is similar but more detailed. The commonly used Lauren classification separates gastric cancers into intestinal type (53%), diffuse type (33%), and unclassified (14%). The intestinal type is associated with chronic atrophic gastritis, severe intestinal metaplasia, and dysplasia, and tends to be less aggressive than the diffuse type. The diffuse type of gastric cancer is more likely to be poorly differentiated and is associated with younger patients and proximal tumors. The Ming classification also is useful and easy to remember, with only two types—expanding (67%) and infiltrative (33%).

Recently, the significance of human epidermal growth factor receptor-2 (HER2) was reported in patients with gastric cancer. In breast cancer, overexpression of HER2 has been reported in 15% to 25% and is well recognized as one of the unfavorable prognostic factors. However, the development of molecular targeted agents such as trastuzumab has improved the survival of HER2 positive patients. Likewise, recently in gastric cancer, HER2 overexpression has been reported in 13% to 30% of patients. According to the result of large clinical trial, Immunohistochemistry (IHC) staining of HER2 has become the important examination for recurrent or metastatic gastric cancer to decide the treatment strategy.

**Pathologic Staging** Ultimately, prognosis is related to pathologic stage. The most widespread system for staging of gastric cancer is the tumor-node-metastasis (TNM) staging system based on depth of tumor invasion, extent of lymph node metastases, and presence of distant metastases. This system was developed by the American Joint Committee on Cancer and the International Union Against Cancer, and has under gone several modifications since it was originally conceived (Table 26-19).

**Clinical Manifestations.** Most patients who are diagnosed with gastric cancer in the United States have advanced stage III or IV disease at the time of diagnosis. The most common symptoms are weight loss and decreased food intake due to anorexia and early satiety. Abdominal pain (usually not severe and often ignored) also is common. Other symptoms include nausea, vomiting, and bloating. Acute GI bleeding is somewhat unusual (5%), but chronic occult blood loss is common and manifests as iron deficiency anemia and heme-positive stool. Dysphagia is common if the tumor involves the cardia of the stomach. Paraneoplastic syndromes such as Trousseau’s syndrome (thrombophlebitis), acanthosis nigricans (hyperpigmentation of the axilla and groin), or peripheral neuropathy are rarely present.

Physical examination typically is normal. Other than signs of weight loss, specific physical findings usually indicate incurability. A focused examination in a patient in whom gastric cancer is a likely part of the differential diagnosis should include an examination of the neck, chest, abdomen, rectum, and pelvis. Cervical, supraclavicular (on the left referred to as Virchow’s node), and axillary lymph nodes may be enlarged, and today can be sampled in the office with fine-needle aspiration cytology. There may be a metastatic pleural effusion, or aspiration pneumonitis in a patient with vomiting and/or obstruction. An abdominal mass could indicate a large (usually T4 incurable) primary tumor, liver metastases, or carcinomatosis (including Krukenberg’s tumor of the ovary). A palpable umbilical nodule (Sister Joseph’s nodule) is pathognomonic of advanced disease, or there may be evidence on exam of malignant ascites. Rectal exam may reveal heme-positive stool and hard nodularity.

**Diagnostic Evaluation.** Distinguishing between peptic ulcer and gastric cancer on clinical grounds alone is usually impossible. Patients over the age of 45 years old who have new-onset dyspepsia, as well as all patients with dyspepsia and alarm symptoms (weight loss, recurrent vomiting, dysphagia, evidence of GI bleeding, or anemia) or with a family history of gastric cancer should have prompt upper endoscopy and biopsy if a mucosal lesion is noted. Essentially, all patients in whom gastric cancer is part of the differential diagnosis should have endoscopy and biopsy. If suspicion for cancer is high and the biopsy is negative, the patient should be re-endoscoped and more aggressively biopsied. In some patients with gastric tumors, upper GI series can be helpful in planning treatment. Although a good double-contrast barium upper GI examination is sensitive for gastric tumors (up to 75% sensitive), in most centers, endoscopy has become the gold standard for the diagnosis of gastric malignancy.

In addition, recent advances in endoscopy have contributed to the earlier diagnosis of gastric cancer. Magnifying endoscopy with narrow-band imaging (NBI) has undergone technological improvements and can observe the microvascular architecture of the mucosa and microsurface pattern of the lesion. Magnifying endoscopy with NBI has been reported to be accurate and reliable in the diagnosis of early gastric cancer. Furthermore, endocytoscopy, a technique allowing microscopic visualization of the mucosal surface, has been developed and has the potential for pathological diagnosis. Another diagnostic innovation is virtual endoscopy which is an imaging examination of the gastrointestinal tract reconstructed by multidetector-row computed tomography. The image of virtual endoscopy is now quite similar to that of upper endoscopy. In the near future, this novel technology may play a role in the screening of the stomach.

Preoperative staging of gastric cancer is best accomplished with abdominal/pelvic CT scanning with IV and oral contrast. MRI is probably comparable. The best way to stage the tumor locally is via EUS, which gives fairly accurate (80%) information about the depth of tumor penetration into the gastric wall, and can usually show enlarged (>5 mm) perigastric and celiac lymph nodes. In some centers, if the tumor is transmural (T3) or involves lymph nodes (enlarged nodes can usually be needled under endoscopic ultrasound guidance), preoperative (neoadjuvant) chemotherapy is given. However, there are limitations to tumor staging with EUS. It largely is operator dependent and may underestimate lymph node involvement because normal-sized nodes (<5 mm) can harbor metastases. EUS is most accurate in distinguishing early gastric cancer (T1) from more advanced tumors.

**Positron Emission Tomography Scanning** Whole-body PET scanning uses the principle that tumor cells preferentially accumulate positron-emitting 18F-fluorodeoxy glucose. This modality is most useful in the evaluation of distant metastasis in gastric cancer but can also be useful in locoregional staging. PET scan is accurate when combined with spiral CT (PET-CT) and should be considered before major surgery in patients with particularly high-risk tumors or multiple medical comorbidities.

**Staging Laparoscopy and Peritoneal Cytology** To some extent, the usefulness of these modalities depends on the individual patient’s situation as well as the treatment philosophy of the cancer team. The fundamental question is “will it make a difference to this patient’s management?” Patients with gastric cancer who undergo R0 resection (i.e., no gross residual
disease) and are found to have positive peritoneal cytology (no gross carcinomatosis) have a much worse prognosis than the cytology negative group (median survival 14.8 months vs. 98.5 months).96 It is controversial how much this information adds prognostically to that of pathologic staging (TNM). Whether this poor prognosis can be improved postresection with aggressive adjuvant treatment (systemic, or local intraperitoneal hyperthermic chemotherapy) is unknown. Unfortunately, it is also unclear how much these patients benefit from gastric resection. Currently peritoneal cytology information is unlikely to change the treatment of patients with gastric cancer, and most patients without detectable distant metastases will have (and should have) gastric resection regardless of the peritoneal cytology results. A quick laparoscopic examination can occasionally reveal small peritoneal implants or liver metastases that were not detected on preoperative imaging studies and, in some patients (e.g., high risk for surgery or impressive carcinomatosis), this will change the operative plan and avoid a major but futile surgical procedure. Laparoscopy may be most useful in patients with proximal tumors or with adenopathy on spiral CT scan.97 An extensive laparoscopic staging procedure, although quite accurate, has not been widely adopted.

**Treatment.** Surgical resection is the only curative treatment for gastric cancer98,99 and most patients with clinically resectable locoregional disease should have gastric resection. Obvious exceptions include patients who cannot tolerate an abdominal operation, and patients with overwhelming metastatic disease. The goal of curative surgical treatment is resection of all tumor (i.e., R0 resection). Thus, all margins (proximal, distal, and radial) should be negative and an adequate lymphadenectomy performed. Generally, the surgeon strives for a grossly negative margin of at least 5 cm. Some gastric tumors, particularly the diffuse variety, are quite infiltrative and tumor cells can extend well beyond the tumor mass; thus, gross margins beyond 5 cm may be desirable. Frozen section confirmation of negative margins is important when performing operation for cure, but it is less important in patients with nodal metastases beyond the N1 nodal basin. It should be strongly emphasized that many patients with positive lymph nodes are cured by adequate surgery. It should also be stressed that often lymph nodes that appear to be grossly involved with tumor turn out to be benign or reactive on pathologic examination. More than 15 resected lymph nodes are required for adequate staging.100 Therapeutic nihilism should be avoided and, in the low-risk patient, an aggressive attempt to resect all tumor should be made. The primary tumor may be resected en bloc with adjacent involved organs (e.g., distal pancreas, transverse colon, and spleen) during the course of curative gastrectomy. Palliative gastrectomy may be indicated in some patients with obviously incurable disease, but most patients presenting with stage IV gastric cancer can be managed without major operation.99,100

**Extent of Gastrectomy** The standard operation for gastric cancer is radical subtotal gastrectomy. Unless required for R0 resection, total gastrectomy confers no additional survival benefit and may have adverse nutritional or quality-of-life consequences, and higher peri-operative morbidity and mortality.98,99 Subtotal gastric resection typically entails ligation of the left and right gastric and gastroepiploic arteries at the origin, as well as the en bloc removal of the distal 75% of the stomach, including the pylorus and 2 cm of duodenum, the greater and lesser omentum, and all associated lymphatic tissue (Fig. 26-56). Reconstruction is usually by Billroth II gastrojejunostomy, but if a small gastric remnant is left, a Roux-en-Y reconstruction is considered. In East Asia especially in Japan, Billroth-I gastroduodenostomy was usually performed after distal gastrectomy. Billroth-I gastroduodenostomy consists of one anastomosis (which is usually straightforward and keeps the duodenum in the food stream). In the United States, traditional surgical teaching eschews gastroduodenostomy following gastric cancer resection because of the possibility of anastomotic recurrence and obstruction. The operative mortality is around 2% to 5%. Radical subtotal gastrectomy is generally deemed to be an adequate cancer operation in most Western countries, provided that tumor-free margins are obtained, >15 lymph nodes are removed, and all gross tumor is resected. In the absence of involvement by direct extension, the spleen and pancreatic tail are not removed.

Total gastrectomy with Roux-en-Y esophagojejunostomy may be required for R0 resection (Fig. 26-57), and may be the best operation for patients with proximal gastric adenocarcinoma. The construction of a jejunal pouch can be beneficial nutritionally, particularly for those patients with a good prognosis.102

![Figure 26-56. A and B, Radical subtotal gastrectomy. vs. = vessels. (Reproduced with permission from Daly JM, Cady B, Low DW (eds): Atlas of Surgical Oncology. St. Louis: Mosby-Year Book, 1993, p 251. Copyright Elsevier.]
Proximal subtotal gastric resection, a technically feasible alternative to total gastrectomy for some proximal gastric tumors, requires an esophagogastrectomy to a vagotomized distal gastric remnant, and the functional outcome is poor. Pyloroplasty in this setting virtually guarantees bile esophagitis, and if the pylorus is left intact, gastric emptying may be problematic. An isoperistaltic jejunal interposition (Henley loop) between the esophagus and antrum could be considered an alternative reconstruction, but, all things considered, total gastrectomy usually results in superior functional, if not oncologic, results for most patients with proximal gastric cancer.

**Extent of Lymphadenectomy** According to the 3rd edition of Japanese classification of gastric carcinoma, lymph node stations are numbered by anatomical definition. Lymph node stations from 1 to 12, and 14V are classified as regional lymph nodes and metastasis of any other lymph node is classified as distant metastasis (M1) (see Fig. 26-4). According to the type of gastrectomy, the definition of extent of lymphadenectomy is different. D1 lymphadenectomy in distal gastrectomy requires the dissection of stations 1 through 7. Furthermore, additional resection of stations 8a, 9, 11p and 12a is needed for D2 lymphadenectomy. D1 lymphadenectomy in total gastrectomy requires dissection of stations 1 through 7 and in D2, from 8a to 12a too. The operation described above (radical subtotal gastrectomy in the Extent of Gastrectomy section), which is by far the most commonly performed procedure in the United States for gastric cancer, is called a D1 resection because it removes the tumor and the perigastric D1 nodes. The standard operation for gastric cancer in Asia and specialized U.S. centers is the D2 gastrectomy, which involves a more extensive lymphadenectomy (removal of the D1 and D2 nodes). In addition to the tissue removed in a D1 resection, the standard D2 gastrectomy removes the peritoneal layer over the anterior mesocolon and selectively over the pancreas, along with nodes along the hepatic and splenic arteries, and the cranial nodes. Splenectomy and distal pancreatectomy are not routinely performed, because this clearly has been shown to increase the morbidity of the operation. The purported survival advantage of D2 gastrectomy in gastric cancer is shown in Table 26-20, which shows the 5-year survival rates for gastric cancer stratified by pathologic stage for the United States and Japan. Unfortunately, the randomized prospective trials that have been performed have not confirmed this survival advantage, but the morbidity and mortality in the D2 group was higher (Table 26-21).

This was mostly attributable to the splenectomy and distal pancreatectomy, which are no longer routinely done as part of the D2 gastrectomy in the United States. However, since D2 lymphadenectomy in total gastrectomy requires the dissection of station 10 which is splenic hilar lymph node as described above, splenectomy is recommended to fulfill the criteria of D2. In Japan, pancreas-preserving splenectomy is generally performed to avoid the severe postoperative complications such as pancreas fistula in patients with advanced upper gastric cancer who underwent total gastrectomy. Some experts have argued that the D2 operation is simply a better staging procedure, and that the apparent improved survival with this more extensive dissection is simply an epiphenomenon of improved pathologic staging. This stage shift suggests that many patients in the U.S. series treated with D1 gastrectomy really had metastatic nodes at the D2 level that went unresected and undetected. Therefore, in the U.S. series, there were patients classified as stage I, who, if they had undergone a D2 gastrectomy, would be classified as stage II; and there were patients classified as stage II, who, if they had undergone a D2 gastrectomy, would be classified as stage III. The stage I survival in the United States would then actually be closer to the (more accurately staged) stage II survival in Japan, because this group includes some patients who really are stage II, but the nodes were not found in the D1 resection. All experts would agree that to avoid understaging of gastric cancer, a minimum of 15 nodes should be resected with the gastrectomy specimen. Despite the lack of strong data from RCTs supporting a survival advantage of D2 gastrectomy for gastric cancer, this

Chemotherapy and Radiation for Gastric Cancer

In general, the actuarial 5-year survival for resected gastric adenocarcinoma stages I, II, and III is about 75%, 50%, and 25%, respectively. Because most surgical patients have stage II disease or greater, it is common to refer gastric cancer patients postoperatively to a medical and/or radiation oncologist. Unfortunately, the existing data suggest that the incremental survival benefit attendant to adjuvant treatment is marginal, particularly in those patients who have had an adequate resection.98,99 In one prospective randomized study, adjuvant treatment with chemotherapy (5-fluorouracil and leucovorin) and radiation (4500 cGy) has demonstrated a survival benefit in resected patients with stage II and III adenocarcinoma of the stomach.100 Unfortunately, only 10% of patients entered in the study actually had D2 gastrectomy, and most (54%) had less than an adequate D1 gastrectomy. Because adequacy of lymphadenectomy has clearly been shown to impact survival, particularly in patients with stage III gastric cancer, it has been suggested that the benefits of adjuvant chemoradiation shown in this study would be vitiated by an adequate operation. Recent clinical trials suggest the potential importance of adjuvant chemotherapy after D2 lymphadenectomy in patients with advanced gastric cancer. These trials compared surgery alone and surgery plus adjuvant chemotherapy including oral fluoropyrimidines for curatively resected advanced gastric cancer. After D2 lymphadenectomy, the benefit of adjuvant chemotherapy has also been established and further improvement in prognosis is expected.105,106 A recently published study from the Japan Clinical Oncology Group showed a 69% overall 5-year survival rate in patients with clinically curable T2b, T3, and T4 gastric cancer, treated with D2 gastrectomy alone (no chemotherapy).106 There was no incremental benefit from para-aortic lymph node dissection. There is no indication for the routine use of radiation alone in gastric cancer as well as several types of cancer, such as colon and lung. In the 1990s, the introduction of novel anticancer agents such as camptothecin, taxanes, third-generation platinums, and new oral fluoropyrimidines, improved the prognosis of unresectable gastric cancer. Recently, although the risk of the toxicities is increased, triple combination chemotherapy is associated with better prognosis than double agent therapy. In the United States, triple chemotherapy consists of 5-FU, cisplatin and docetaxel and is now recognized as a standard first-line regimen. In Europe, triple therapy is more often epirubicin, cisplatin, and 5-FU. Sometimes 5-FU may be replaced by capecitabine which is an oral fluoropyrimidine, and cisplatin can be replaced by oxaliplatin which does not require hydration, respectively. Neo-adjuvant treatment of gastric adenocarcinoma is being evaluated, particularly in patients with clinical T3 or N1 disease. It is likely that targeted molecular agents will have an increasing role in treating gastric cancer. Recently, Trastuzumab, a humanized molecular antibody reactive against the extracellular domain of HER2, increased the effectiveness of cytotoxic chemotherapy in patients with advanced gastric cancer. Other large trials are ongoing. Determination of HER2 gene amplification status may have prognostic significance.

Endoscopic Resection

It has been demonstrated initially at numerous East Asian centers that some patients with early gastric cancer can be adequately treated by an endoscopic mucosal resection (EMR). EMR is a minimally invasive procedure that provides curative resection and has dramatically changed the treatment of early gastric cancer. EMR is indicated for patients in whom the probability of lymph node metastasis is low. According to the Japanese treatment guidelines for gastric cancer, EMR is a standard treatment for differentiated mucosal gastric cancer measuring less than 2 cm and without signs of ulceration, which has almost no risk of lymph node metastasis. En bloc resection is required to evaluate the surgical margin for confirmation of curative resection. Furthermore, the development of endoscopic submucosal dissection (ESD) allows en bloc resection of larger tumors. Therefore, the indications for endoscopic treatment of patients with gastric cancer may be broadened. New indications for minimally invasive treatment will require evaluation before implementation. Small tumors (<3 cm) confined to the mucosa have an extremely low chance of lymph node metastasis (3%), which approaches the operative mortality rate for gastrectomy. If the resected specimen demonstrates no ulceration, no penetration of the muscularis mucosae, no lymphatic invasion, and size <3 cm, then the risk of lymph node metastases is less than 1%. Thus, some patients with early gastric cancer might be better treated with the endoscopic technique. Currently, this should be limited

to patients with tumors <2 cm in size that are node negative and confined to the mucosa on EUS, in the absence of other gastrointestinal lesions. The addition of laparoscopic lymph node sampling may be considered in selected patients.

**Prognosis.** The 5-year survival for gastric adenocarcinoma has increased from 15% to 22% in the United States over the past 25 years. Survival is dependent on pathologic stage (TNM stage) and degree of tumor differentiation. Other important prognostic factors are sex, age, primary gastric tumor site, tumor size, and tumor depth.

Palliative gastrectomy may be indicated in some patients with obviously incurable disease, but most patients presenting with stage IV gastric cancer can be managed without major operation.\(^9,10^\)

**Screening for Gastric Cancer.** In Japan, it clearly has been shown that patients participating in gastric cancer screening programs have a significantly decreased risk of dying from gastric cancer. Thus, screening is effective in a high-risk population. Screening the general population in the United States (a low-risk country) does not make sense, but patients clearly at risk for gastric cancer probably should have periodic endoscopy and biopsy. This includes patients with familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer, gastric adenomas, Ménétrier’s disease, intestinal metaplasia or dysplasia, and remote gastrectomy or gastrojejunostomy.

**Gastric Lymphoma**

Gastric lymphomas generally account for about 4% of gastric malignancies. Over half of patients with non-Hodgkin’s lymphoma have involvement of the GI tract. The stomach is the most common site of primary GI lymphoma, and over 95% are non-Hodgkin’s type. Most are B-cell type, thought to arise in mucosa associated lymphoid tissue (MALT), although most high-grade gastric lymphomas are without any characteristics of the low-grade MALT neoplasm.\(^9,10^\) About half of gastric lymphomas are histologically low grade, and about half are high grade. Interestingly, the normal stomach is relatively devoid of lymphoid tissue. However, in the setting of chronic gastritis, the stomach acquires MALT, which can undergo malignant degeneration. Again, *H. pylori* is thought to be the culprit. In populations with a high incidence of gastric lymphoma, there is a high incidence of *H. pylori* infection; patients with gastric lymphoma also usually have *H. pylori* infection.\(^10^\)

Low-grade MALT lymphoma, essentially a monoclonal proliferation of B cells, presumably arises from a background of chronic gastritis associated with *H. pylori*. These relatively innocuous tumors then undergo degeneration to high-grade lymphoma, which is the usual variety seen by the surgeon. Remarkably, when the *H. pylori* is eradicated and the gastritis improves, the low-grade MALT lymphoma often disappears. Thus, low-grade MALT lymphoma is not a surgical lesion. Careful follow-up is necessary particularly in those lesions with a t(11;18) translocation, thought to be a risk factor for a more aggressive MALT lesion. If low-grade lymphoma persists after *H. pylori* eradication, radiation should be considered for disease clinically confined to the stomach (stage I), while chemotherapy with or without radiation is used for more advanced lesions (Fig. 26-58).

Patients with high-grade gastric lymphoma require aggressive oncologic treatment for cure and present with many of the same symptoms as gastric cancer patients. However, systemic symptoms such as fever, weight loss, and night sweats occur in about 50% of patients with gastric lymphoma. The tumors may bleed and/or obstruct. Lymphadenopathy and/or organomegaly suggest systemic disease. Diagnosis is by endoscopy and biopsy. Much of the tumor may be submucosal, and an assiduous attempt at biopsy is necessary. Primary lymphoma is usually nodular with enlarged gastric folds. A diffusely infiltrative process akin to linitis plastica is more suggestive of secondary gastric involvement by lymphoma. A diligent search for extragastric disease is necessary before the diagnosis of localized primary gastric lymphoma is made. This includes EUS; CT scanning of the chest, abdomen, and pelvis; and bone marrow biopsy. Most patients with high-grade gastric lymphoma are currently treated with chemotherapy and radiation, without surgical resection. Treatment-related perforation or bleeding is unusual but recognized. For disease limited to the stomach and regional nodes, radical subtotal gastrectomy may be performed, especially for bulky tumors with bleeding and/or obstruction. Palliative gastrectomy for tumor complications also has a role. Certainly, a multidisciplinary team should be involved with the treatment plan for patients with primary gastric lymphoma.

**Gastrointestinal Stomal Tumor**

GISTs arise from interstitial cells of Cajal (ICC) and are distinct from leiomyoma and leiomyosarcoma, which arise from smooth muscle.\(^10^\) Prognosis in patients with GIST tumors depends mostly on tumor size and mitotic count, and metastasis, when it occurs, is typically by the hematogenous route. Any lesion >1 cm can behave in a malignant fashion and may recur. Thus, all GISTs are best resected along with a margin of normal tissue. Almost all GISTs (and almost no smooth muscle tumors) express c-KIT (CD117) or the related PDGF receptor A, as well as CD34; almost all smooth muscle tumors (and almost no GISTs) express actin and desmin. These markers can often be detected on specimens obtained by fine-needle aspiration and are useful in differentiating between GIST and smooth muscle tumor histopathologically. Lesions that are definitively leiomyoma by current histopathologic criteria are adequately treated by enucleation. Lesions that are definitively GIST or leiomyosarcoma are best treated by resection with negative margins. Most equivocal lesions should be resected to provide that the patient is a reasonable operative risk.

Two-thirds of all GISTs occur in the stomach. Epithelial cell stromal GIST is the most common cell type arising in the stomach, and cellular spindle type is the next most common. The glomus tumor type is seen only in the stomach.

GISTs are submucosal tumors that are slow growing. Smaller lesions are usually found incidentally, although they occasionally may ulcerate and cause impressive bleeding. Larger lesions generally produce symptoms of weight loss, abdominal pain, fullness, early satiety, and bleeding. An abdominal mass may be palpable. Metastasis is by the hematogenous route, often to liver and/or lung, although positive lymph nodes are occasionally seen in resected specimens.

Diagnosis is by endoscopy and biopsy, although the interpretation of the latter may be problematic. EUS may be helpful, but symptomatic tumors and tumors >1 cm in size should be removed. Metastatic work-up entails CT of the chest, abdomen, and pelvis (chest X-ray may suffice in lieu of CT of the chest). Most gastric GISTs occur in the body of the stomach, but they also can occur in the fundus or antrum. They are almost always solitary. Wedge resection with clear margins is adequate surgical treatment. True invasion of adjacent structures by the primary tumor is evidence of malignancy. If safe, en bloc resection of involved surrounding organs is appropriate to remove all tumor when the primary is large and invasive. Five-year survival
following resection for GIST is about 50%. Most patients with low-grade lesions are cured (80% 5-year survival), but most patients with high-grade lesions are not (30% 5-year survival).

According to the tumor size and mitotic count, the risk of aggressive behavior was classified into four groups. Very low risk was defined as \(<2\) cm and \(<5/50\) HPF (high-power field) and low risk was defined as \(2\) to \(5\)cm and \(<5/50\) cm. Intermediate risk was defined as \(<5\) cm and \(6\) to \(10/50\) HPF or \(5\) to \(10\) cm and \(>5/50\) HPF. And high risk was defined as \(>5\) cm and \(>5/50\) HPF, \(>10\) cm with any mitotic rate or \(>10/50\) HPF with any size. It was known that the risk of recurrence differs by the primary site of the tumor. Recently, new classification based on tumor location, size, and mitotic rate has been used to evaluate the risk of recurrence and metastasis.\(^{110b}\)

GISTs are usually positive for the protooncogene, c-kit, a characteristic shared with the ICC. Imatinib (Gleevec), a chemotherapeutic agent that blocks the activity of the tyrosine kinase product of c-kit, yields excellent results in many patients with metastatic or unresectable GIST. Up to 50% of treated patients develop resistance to imatinib by 2 years, and several newer agents show promise for patients with refractory disease. The efficacy of imatinib as adjuvant therapy for high risk patients has been demonstrated in large clinical trials.\(^{110c,110d}\) According to the NCCN guidelines for soft tissue sarcoma (version 2, 2012), the administration of imatinib was recommended in high risk groups as an adjuvant therapy.\(^{110d}\) An algorithm for the treatment of patients with GIST is shown in Fig. 26-59.

**Gastric Carcinoid Tumors**\(^{111-113}\)

Compared to midgut and hindgut locations, carcinoid tumors of the stomach are rather unusual. Gastric carcinoids comprise about 1% of all carcinoid tumors and less than 2% of gastric neoplasms. They arise from gastric enterochromaffin-like (ECL) cells and some have malignant potential. The apparent

---

SPECIFIC CONSIDERATIONS

UNIT II

PART II

inci-cidence of gastric carcinoids is increasing, perhaps related to the more common use of upper endoscopy and/or the increasing use of acid suppressive medication. The latter may cause hypergastrinemia, and gastrin has a recognized trophic effect on gastric ECL cells. Gastric carcinoid is equivalent to neuroendocrine tumor (NET) or well-differentiated neuroendocrine tumor/carcinoma according to WHO classification.

Gastric carcinoids are classified into one of three different types. Type I is the most common type of gastric carcinoid, accounting for about 75% of patients. Type I carcinoids occur in patients with chronic hypergastrinemia secondary to pernicious anemia or chronic atrophic gastritis. These lesions occur more frequently in women, are often multiple and small, and have low malignant potential (<5% metastasize). The role of long-term acid suppression with resultant hypergastrinemia in the pathogenesis of type I gastric carcinoids is unclear.

Type II gastric carcinoids are associated with MEN1 and ZES. These lesions also tend to be small and multiple, but have a somewhat higher malignant potential than type I lesions (10% metastasize). Type II gastric carcinoids are more strongly associated with MEN1; they are quite uncommon in patients with sporadic ZES without MEN1. Gastric acid hypersecretion, hypergastrinemia, and gastric carcinoid imply gastrinoma until proven otherwise.

Type III gastric carcinoids are sporadic tumors. They are most often solitary (usually >2 cm) and occur more commonly in men. They are not associated with hypergastrinemia and biopsy shows a heterogeneous cell population. Most patients have nodal or distant metastases at the time of diagnosis, and some present with symptoms of carcinoid syndrome.

Gastric carcinoids are usually diagnosed with endoscopy and biopsy. Some tumors are submucosal and may be quite small. They are often confused with heterotopic pancreas or small leiomyomas. Biopsy may be difficult because of the submucosal location, and EUS can be helpful in defining the size and depth of the lesion. Plasma chromogranin A levels are elevated in patients with gastric carcinoid. CT scan and octreotide scan are useful for staging.

Gastric carcinoids should be resected. Small lesions confined to the mucosa (typically type I or type II lesions) may be treated endoscopically with EMR if there are only a few lesions (<5) and if margins are histologically negative. Careful follow-up is necessary. Larger lesions should be removed by D1 or D2 gastrectomy. Survival is excellent for node-negative patients (>90% 5-year survival); node-positive patients have a 50% 5-year survival. Gastrinoma should be resected if located in patients with type II carcinoid. The 5-year survival for patients with type I gastric carcinoid is close to 100%; for patients with type III lesions, the 5-year survival is less than 50%. Somatostatin analogue treatment is useful in controlling the symptoms of carcinoid syndrome but apparently does not prolong survival in patients with metastatic gastric carcinoid. Surgical debulking may have a role in selected patients with metastatic disease. Because somatostatin has an antiproliferative effect on gastric ECL cells, there may be a possible primary treatment role for octreotide in poor-risk surgical patients with gastric carcinoid.

BENIGN GASTRIC NEOPLASMS

Leiomyoma
The typical leiomyoma is submucosal and firm. If ulcerated, it has an umbilicated appearance and may bleed. Histologically, these
lesions appear to be of smooth muscle origin. Lesions <2 cm are usually asymptomatic and benign. Larger lesions have greater malignant potential and a greater likelihood to cause symptoms such as bleeding, obstruction, or pain. Asymptomatic lesions <2 cm may be carefully observed or enucleated if fine-needle aspiration and immune markers confirm smooth muscle tumor; larger lesions and symptomatic lesions should be removed by wedge resection (often possible laparoscopically). When lesions thought to be leiomyoma are observed rather than resected, the patient should be made aware of their presence and the small possibility for malignancy.

**Lipoma**
Lipomas are benign submucosal fatty tumors that are usually asymptomatic, found incidentally on upper GI series or EGD. Endoscopically, they have a characteristic appearance; there also is a characteristic appearance on EUS. Excision is unnecessary unless the patient is symptomatic.

**Gastric Motility Disorders**
Gastric motility disorders include delayed gastric emptying (gastroparesis), rapid gastric emptying, and motor and sensory abnormalities (e.g., functional dyspepsia). Surgically relevant secondary disorders of gastric motility (e.g., dumping, gastric stasis, and Roux syndrome) are discussed under Postgastrectomy Problems. Gastroparesis is the most surgically relevant primary disorder of gastric motility.114.115

Most patients with primary gastroparesis present with nausea, vomiting, bloating, early satiety, and/or abdominal pain. Eighty percent of these patients are women; some are diabetic. Postprandial vomiting significantly complicates the management of blood glucose in the latter group, predisposing to hypoglycemia following preprandial insulin. In patients with gastroparesis, it is important to rule out mechanical gastric outlet obstruction, and small-bowel obstruction. An upper GI series may suggest slow gastric emptying and relative atony, or it may be normal. EGD may show bezoars or retained food but is frequently normal. Gastric emptying scintigraphy shows delayed solid emptying, and often delayed liquid emptying. Gastroparesis can be a manifestation of a variety of problems (Table 26-22). Medical treatment includes promotility agents, antiemetics, and, perhaps, botulinum injection into the pylorus.

If the diabetic gastroparetic patient is not a candidate for pancreas transplant, both gastrostomy (for decompression) and jejunostomy tubes (for feeding and prevention of hypoglycemia) can be effective. Other surgical options include implantation of a gastric pacemaker, and gastric resection. Generally, gastric resection should be done only after other therapeutic options have been exhausted.

**Massive Upper Gastrointestinal Bleeding**
Although there have been arbitrary definitions of “massive” upper GI bleeding put forth, perhaps the most practical definition in the current era would be acute bleeding proximal to the ligament of Treitz, which requires blood transfusion. In multiple series, the stomach and proximal duodenum is by far the most common source of pathology associated with this diagnosis. The most common causes of acute GI bleeding in emergency room or hospitalized patients are peptic ulcer, gastritis, Mallory-Weiss syndrome, and esophagogastric varices. Less common causes include benign or malignant neoplasm, angiodysplasia, Dieulafoy’s lesion, portal gastropathy, Ménetrier’s disease, and watermelon stomach. Arterioenteric fistula should always be considered in the patient who has an aortic graft or who has undergone repair of a visceral artery aneurysm.

The most important issues in the early hospital management of patients with acute upper GI bleeding are resuscitation and risk stratification. Large-bore IV access and Foley catheterization is accomplished, and nasogastric intubation is considered. Risk stratification is essentially accomplished by answering the following questions:

a. What is the magnitude and acuity of the hemorrhage? Hypotension, tachycardia, oliguria, low hematocrit, pallor, altered mentation, and/or hematemesis suggest a large blood loss that has occurred over a short period of time. This is a high-risk situation.
b. Does the patient have significant chronic disease, particularly lung, liver, kidney, and/or heart disease, which compromises physiologic reserve? If yes, this is a high-risk situation.
c. Is the patient anticoagulated, or immunosuppressed? If yes, this is a high-risk situation.
d. On endoscopy, is the patient bleeding from varices, or is there active bleeding, or is there a visible vessel, or is there a deep ulcer overlying a large vessel (e.g., posterior duodenal ulcer overlying the gastroduodenal artery)? Could the patient be bleeding from an Arterio enteric fistula? If yes, this is a high-risk situation.
If judged to be low risk, most patients will stop bleeding with supportive treatment and IV PPI. Selected patients may be discharged from the emergency room and managed on an outpatient basis.

If the patient is judged to be high risk based on one or more of the questions previously listed, then the following should be done immediately:

1. Type and cross-match for transfusion of blood products.
2. Admit to ICU or monitored bed in specialized unit.
3. Consult surgeon.
4. Consult gastroenterologist.
5. Start continuous infusion of PPI.
6. Perform upper endoscopy within 12 hours, after resuscitation and correction of coagulopathy. Endoscopic hemostasis should be considered in most high-risk patients with acute upper GI bleeding.

Although the surgeon should be involved early in the hospital course of all high-risk patients with acute upper GI bleeding, most of these patients will be adequately managed without operation. Mucosal lesions can usually be controlled with endoscopic hemotherapy and medical management. Occasionally, arteriography can be helpful. Operation for bleeding ulcer is discussed previously (see Operation for Bleeding Peptic Ulcer and Fig. 26-43).

Isolated Gastric Varices

Isolated gastric varices are those that occur in the absence of esophageal varices and are classified as type I (fundic) or type II (distal to fundus including proximal duodenum). The presence of isolated gastric varices is usually associated with portal hyper-tension or splenic vein thrombosis. Although there is a significant bleeding risk from isolated gastric varices on long-term follow-up, there is no indication for the routine application of prophylactic measures.

Patients with acute upper GI bleeding from isolated gastric varices should be considered high risk. Although data are limited, octreotide and/or vasopressin infusion may decrease bleeding, if tolerated. Balloon tamponade with a Sengstaken-Blakemore tube may provide temporary control of exsanguinating hemorrhage from type isolated gastric varices, but if this is used, endotracheal intubation for airway protection is prudent. Endoscopic treatment with sclerotherapy or varix ligation is less successful than in esophageal varices, but should be considered. Interventional radiology should be consulted and balloon occluded retrograde transvenous obliteration considered. A transjugular intrahepatic portosystemic shunt may be useful if there is nonsegmental portal hypertension. If the patient has splenic vein thrombosis and left-sided (sinistral) or segmental portal hypertension, splenectomy is quite effective in controlling bleeding from isolated gastric varices. The operative mortality is 5%. Liver transplantation should always be considered in the cirrhotic patient.

Hypertrophic Gastropathy (Ménétrier’s Disease)

There are two clinical syndromes characterized by epithelial hyperplasia and giant gastric folds: ZES and Ménétrier’s disease. The latter is characteristically associated with protein-losing gastropathy and hypochlorhydria. There are large rugal folds in the proximal stomach, and the antrum is usually spared. Mucosal biopsy shows diffuse hyperplasia of the surface mucus-secreting cells and usually decreased parietal cells (Fig. 26-60). It has recently been suggested that Ménétrier’s disease is caused by local overexpression of transforming growth factor alpha in the gastric mucosa, which stimulates the epidermal growth factor receptor, a receptor tyrosine kinase, on gastric SECs. This results in the selective expansion of surface mucous cells in the gastric body and fundus. A few patients with this unusual disease have been successfully treated with the epidermal growth factor receptor blocking monoclonal antibody cetuximab.

Most patients with Ménétrier’s disease are middle-aged men who present with epigastric pain, weight loss, diarrhea, and hypoproteinemia. There may be an increased risk of gastric cancer. Sometimes, the disease regresses spontaneously. Gastric resection may be indicated for bleeding, severe hypoproteinemia, or cancer.

Watermelon Stomach (Gastric Antral Vascular Ectasia)

The parallel red stripes atop the mucosal folds of the distal stomach give this rare entity its sobriquet. Histologically, gastric antral vascular ectasia (GAVE) is characterized by dilated mucosal blood vessels that often contain thrombi, in the lamina propria. Mucosal fibromuscular hyperplasia and hyalinization often are present (Fig. 26-61). The histologic appearance can resemble portal hypertensive gastropathy, but the latter usually affects the proximal stomach, whereas watermelon stomach predominantly affects the distal stomach. Beta blockers and nitrates, useful in the treatment of portal hypertensive gastropathy, are ineffective in patients with gastric antral vascular ectasia. Patients with GAVE are usually elderly women with chronic GI blood loss requiring transfusion. Most have an associated autoimmune connective tissue disorder, and at least 25% have chronic liver disease. Nonsurgical treatment options include estrogen and progesterone, and endoscopic treatment with the neodymium yttrium-aluminum garnet (Nd:YAG) laser or argon plasma coagulator. Antrectomy may be required to control blood loss, and this operation is quite effective but carries increased morbidity in this elderly patient group. Patients with portal hyper-tension and antral vascular ectasia should be considered for transjugular intrahepatic portosystemic shunt (TIPSS).

Figure 26-60. Mucosal biopsy in Ménétrier’s disease. [Reproduced with permission from Goldman H: Mucosal hypertrophy and hyperplasia of the stomach, in Ming S-C, Goldman H (eds): Pathology of the Gastrointestinal Tract, 2nd ed. Baltimore: Williams & Wilkins, 1998, p 577.]
Dieulafoy’s Lesion
Dieulafoy’s lesion is a congenital arteriovenous malformation characterized by an unusually large tortuous submucosal artery. If this artery is eroded, impressive pulsatile bleeding may occur. To the endoscopist or surgeon, this appears as a stream of arterial blood emanating from what appears grossly to be a normal gastric mucosa. The lesion typically occurs in middle-aged or elderly men and may be more common in patients with liver disease. Patients typically present with upper GI bleeding, which may be intermittent, and endoscopy can miss the lesion if it is not actively bleeding. Treatment options include endoscopic hemostatic therapy, angiographic embolization, or operation. At surgery, the lesion may be oversewn or resected.

Bezoars/Diverticula
Bezoars are concretions of indigestible matter that accumulate in the stomach. Trichobezoars, composed of hair, occur most commonly in young women who swallow their hair (Fig. 26-62). Phytobezoars are composed of vegetable matter and, in the United States, are usually seen in association with gastroparesis or gastric outlet obstruction. They also are associated with persimmon ingestion. Most commonly, bezoars produce obstructive symptoms, but they may cause ulceration and bleeding. Diagnosis is suggested by upper GI series and confirmed by endoscopy. Treatment options include enzyme therapy (papain, cellulase, or acetylcysteine), endoscopic disruption and removal, or surgical removal.

Gastric diverticula are usually solitary and may be congenital or acquired. Congenital diverticula are true diverticula and contain a full coat of muscularis propria, whereas acquired diverticula (perhaps caused by pulsion) usually have a negligible outer muscle layer. Most gastric diverticula occur in the posterior cardia or fundus (Fig. 26-63) and are usually asymptomatic. However, they can become inflamed and may produce pain or bleeding. Perforation is rare. Asymptomatic diverticula do not require treatment, but symptomatic lesions should be removed. This can often be done laparoscopically.

Foreign Bodies
Ingested foreign bodies are usually asymptomatic. Removal of sharp or large objects should be considered. This can usually be done endoscopically, with an overtube technique.
Recognized dangers include aspiration of the foreign body during removal, and rupture of drug-containing bags in “body packers.” Both complications can be fatal. Surgical removal is recommended in body packers, and in patients with large jagged objects. Corrosive objects (e.g., watch batteries) should be removed promptly.

**Mallory-Weiss Syndrome**
The Mallory-Weiss lesion is a longitudinal tear in the mucosa of the GE junction. It is presumably caused by forceful vomiting and/or retching, and is commonly seen in alcoholics. It presents with upper GI bleeding, often with hematemesis. Endoscopy confirms the diagnosis and may be useful in controlling the bleeding, but 90% of patients stop bleeding spontaneously. Other options to control the bleeding include balloon tamponade, angiographic embolization, or selective infusion of vasopressin, systemic vasopressin, and operation. Surgical treatment consists of oversewing the bleeding lesion through a long gastrostomy.

**Volvulus**
Gastric volvulus is a twist of the stomach that usually occurs in association with a large hiatal hernia. It also can occur in patients with an unusually mobile stomach without hiatal hernia. Typically, the stomach twists along its long axis (organoaxial volvulus), and the greater curvature flips up (Fig. 26-64C). If the stomach twists around the transverse axis, it is called mesenteroaxial rotation (Fig. 26-64A and Fig. 26-64B). Often, volvulus is a chronic condition that can be surprisingly asymptomatic. In these instances, expectant nonoperative management is typically advised, especially in the elderly. The risk of strangulation and infarction has been overestimated in asymptomatic patients. Symptomatic patients should be considered for operation, especially if the symptoms are severe and/or progressive. Patients may present with symptoms of pain and pressure related to the intermittently distending and poorly emptying twisted stomach. Pressure on the lung may produce dyspnea, pressure on the pericardium may produce palpitations, and pressure on the esophagus may produce dysphagia. Symptoms are often relieved with vomiting or passage of a nasogastric tube. Gastric infarction is a surgical emergency, and the patient can be moribund. Gastric necrosis may be extensive or focal. With or without gastropexy, elective operation for gastric volvulus usually involves reduction of the stomach and repair of hiatal hernia. Gastropexy alone may be considered for high-risk patients since it can nearly always be performed laparoscopically and may be surprisingly effective in relieving mechanical symptoms.

**GASTROSTOMY**
A gastrostomy is performed either for alimentation or for gastric drainage/decompression. Gastrostomy may be done percutaneously, laparoscopically, or via open technique. Currently, percutaneous endoscopic gastrostomy is the most common method used. The open techniques include the Stamm method (Fig. 26-65), the Witzel method (Fig. 26-66), and the Janeway method (Fig. 26-67). The last method is meant to create a permanent stoma that can be intubated as needed, but does not drain spontaneously. The Janeway gastrostomy is more complicated than the other open techniques, and is rarely necessary. By far the most common surgical technique is the Stamm gastrostomy, which can be performed open or laparoscopically.

Complications of gastrostomy include infection, dislodgment, leakage with peritonitis, and aspiration pneumonia. Although gastrostomy tubes usually do prevent tense gastric dilatation, they may not adequately drain the stomach, especially when the patient is bedridden.

**POSTGASTRECTOMY PROBLEMS**

**Dumping Syndrome**
Dumping is a phenomenon caused by the destruction or bypass of the pyloric sphincter. However, other factors undoubtedly play a role because dumping can occur after operations that
preserve the pylorus, such as parietal cell vagotomy. The appropriate stimulus can provoke dumping symptoms, even in some patients who have not undergone surgery. Clinically significant dumping occurs in 5% to 10% of patients after pyloroplasty, pyloromyotomy, or distal gastrectomy, and consists of a constellation of postprandial symptoms ranging in severity from annoying to disabling. The symptoms are thought to be the result of the abrupt delivery of a hyperosmolar load into the small bowel due to ablation of the pylorus or decreased gastric compliance. Typically, 15 to 30 minutes after a meal, the patient becomes diaphoretic, weak, light-headed, and tachycardic. These symptoms may be ameliorated by recumbence or saline infusion. Crampy abdominal pain is not uncommon and diarrhea often follows. This is referred to as early dumping, and should be distinguished from postprandial (reactive) hypoglycemia, also called late dumping, which usually occurs later (2–3 hours following a meal), and is relieved by the administration of sugar. A variety of hormonal aberrations have been observed in early dumping, including increased VIP, CCK, neurotensin, peripheral hormone peptide YY, renin-angiotensin-aldosterone, and decreased atrial natriuretic peptide. Late dumping is associated with hypoglycemia and hyperinsulinemia.

The medical therapy for the dumping syndrome consists of dietary management and somatostatin analogue (octreotide). Often, symptoms improve if the patient avoids liquids during meals. Hyperosmolar liquids (e.g., milk shakes) may be particularly troublesome. There is some evidence that adding dietary fiber compounds at mealtime may improve the syndrome. If dietary manipulation fails, the patient is started on octreotide, 100 μg subcutaneously twice daily. This can be increased up to 500 μg twice daily if necessary. The long-acting depot octreotide preparation is useful. Octreotide not only ameliorates the abnormal hormonal pattern seen in patients with dumping symptoms, but also promotes restoration of a fasting motility pattern in the small intestine (i.e., restoration of the MMC). The α-glucosidase inhibitor acarbose may be particularly helpful in ameliorating the symptoms of late dumping.

Only a very small percentage of patients with dumping symptoms ultimately require surgery. Most patients improve with time (months and even years), dietary management, and medication.
Therefore, the surgeon should not rush to reoperate on the patient with dumping symptoms. Multidisciplinary nonsurgical management must be optimized first. Before reoperation, a period of in-hospital observation is useful to define the severity of the patient’s symptoms, and patient compliance with prescribed dietary and medical therapy.

The results of remedial operation for dumping are variable and unpredictable. There are a variety of surgical approaches, none of which work consistently well. Additionally, there is not a great deal of experience reported in the literature with any of these methods. Long-term follow-up is rare. Patients with disabling refractory dumping after gastrojejunostomy can be considered for simple takedown of this anastomosis provided that the pyloric channel is open endoscopically. The reversed intestinal segment is rarely used today—and rightly so. This operation interposes a 10-cm reversed segment of intestine between the stomach and the proximal small bowel. This slows gastric emptying, but often leads to obstruction, requiring reoperation. Isoperistaltic interposition (Henley loop) has not been successful in ameliorating severe dumping over the long term. The Roux-en-Y gastrojejunostomy is associated with delayed gastric emptying, probably on the basis of disordered motility in the Roux limb. Taking advantage of this disordered physiology, surgeons have used this operation successfully in the management of the dumping syndrome. Although this is probably the procedure of choice in the small group of patients requiring operation for severe dumping following gastric resection, gastric stasis may result, particularly if a large gastric remnant is left. In the presence of significant gastric acid secretion, marginal ulceration is common after both jejunal interposition and Roux-en-Y procedures; thus concomitant vagotomy and hemigastrectomy should be considered. The theoretical possibility of treating postpyloroplasty dumping with a Roux-en-Y to the proximal duodenum (the duodenal switch, a potentially reversible operation) has not yet been reported (Fig. 26-68). Because pyloric ablation seems to be the dominant factor in the etiology of dumping, it is not surprising that conversion of Billroth II to Billroth I anastomosis has not been successful in the treatment of dumping.

Diarrhea

Diarrhea following gastric surgery may be the result of truncal vagotomy, dumping, or malabsorption. Truncal vagotomy is associated with clinically significant diarrhea in 5% to 10% of patients. It occurs soon after surgery and usually is not associated with other symptoms, a fact that helps to distinguish it from dumping. The diarrhea may be a daily occurrence, or there may be significant periods of relatively normal bowel function. The symptoms tend to improve over the months and years after the index operation. The cause of postvagotomy diarrhea is unclear. Possible mechanisms include intestinal dysmotility and accelerated transit, bile acid malabsorption, rapid gastric emptying, and bacterial overgrowth. The latter problem is facilitated by decreased gastric acid secretion and (even small) blind loops. Although bacterial overgrowth can be confirmed with the hydrogen breath test, a simpler test is an empirical trial of oral antibiotics. Some patients with postvagotomy diarrhea respond to cholestyramine, while in others codeine or loperamide may be useful. Octreotide should also be tried. Another theoretical cause of diarrhea following gastric surgery is fat malabsorption due to acid inactivation of pancreatic enzymes or poorly coordinated mixing of food and digestive juices. This can be confirmed with a qualitative test for fecal fat and treated with acid suppression. Postvagotomy diarrhea usually does not respond to treatment with pancreatic enzymes. In the rare patient who is debilitated by postvagotomy diarrhea unresponsive to medical management, operation might be considered but outcomes can be problematic. The operation of choice is probably a 10-cm reversed jejunal interposition placed in continuity 100 cm distal to the ligament of Treitz. Another option is the onlay antiperistaltic distal ileal graft. Both operations can cause obstructive symptoms and/or bacterial overgrowth.127B

GastriC Stasis128,129

GastriC stasis following surgery on the stomach may be due to a problem with gastric motor function or caused by an obstruction. The gastric motility abnormality could have been preexisting and unrecognized by the operating surgeon. Alternatively, it may be secondary to deliberate or unintentional vagotomy, or resection of the dominant gastric pacemaker. An obstruction may be mechanical (e.g., anastomotic stricture, efferent limb kink from adhesions or constricting mesocolon, or a proximal small-bowel obstruction) or functional (e.g., retrograde peristalsis in a Roux limb). Gastric stasis presents with vomiting (often of undigested food), bloating, epigastric pain, and weight loss.

The evaluation of a patient with suspected postoperative gastric stasis includes EGD, upper GI and small bowel series, gastric emptying scan, and gastric motor testing. Endoscopy shows gastritis and retained food or bezoar. The anastomosis and efferent limb should be evaluated for stricture or narrowing. A dilated efferent limb suggests chronic stasis, either from a motor abnormality (e.g., Roux syndrome) or mechanical small bowel obstruction (e.g., chronic adhesion). If the problem is thought to be primarily a disorder of intrinsic motor function, newer techniques such as EGG and GI manometry should be considered, but chronic distal mechanical obstruction may result in disordered motility in the proximal organ confounding interpretation.

Once mechanical obstruction has been ruled out, medical treatment is successful in most cases of motor dysfunction following previous gastric surgery. This consists of dietary modification and promotility agents. Intermittent oral antibiotic therapy may be helpful in treating bacterial overgrowth, with its attendant symptoms of bloating, flatulence, and diarrhea. Gastroparesis following V + D may be treated with subtotal gastrectomy but simple loop gastrojejunostomy (GJ) should be tried if previous drainage was pyloroplasty. Billroth II anastomosis with Braun enteroenterostomy may be preferable to Roux-en-Y reconstruction after subtotal gastrectomy for gastric stasis but bile reflux can still occur. Regeneration of gastric stasis is often associated with persistent emptying problems that may subsequently require near-total or total gastrectomy, a nutritionally unattractive option. Delayed gastric emptying following ulcer surgery (V + D or V + A) may represent an anastomotic stricture (often due to recurrent ulcer), or proximal small bowel obstruction. The latter should be dealt with at reoperation. Recurrent ulcer usually responds to medical therapy with PPI and abstinence from NSAIDs, aspirin, and smoking. Endoscopic dilation is occasionally helpful. Gastroparesis following subtotal gastric resection is best treated with near-total (95%) or total gastric resection and Roux-en-Y reconstruction. If total gastrectomy is performed, a jejunal reservoir should be fashioned. Gastric pacing is promising, but it has not achieved widespread clinical usefulness in the treatment of postoperative gastric atony.

Bile Reflux Gastritis and Esophagitis

Most patients who have undergone ablation or resection of the pylorus have bile in the stomach on endoscopic examination, along with some degree of gross or microscopic gastric inflammation. Therefore, attributing postoperative symptoms to bile reflux is problematic because most asymptomatic patients have bile reflux as well. However, it is generally accepted that a small subset of patients have bile reflux gastritis, and present with nausea, bilious vomiting, and epigastric pain, and quantitative evidence of excess enterogastric reflux. Curiously, symptoms often develop months or years after the index operation. The differential diagnosis includes afferent or efferent loop obstruction, gastric stasis, and small-bowel obstruction. Plain abdominal X-rays, upper endoscopy, upper GI series, abdominal CT scan, and gastric emptying scans are helpful in evaluating these possibilities.

Dysfunction of the cardia is one of the causes of bile reflux esophagitis in patients after gastrectomy. Proximal subtotal gastrectomy with esophagoantral anastomosis should be avoided, and if limited resection of the GE junction is performed, the pylorus should be left intact.

Bile reflux may be quantified with gastric analysis or esophageal impedance testing or with scintigraphy (bile reflux scan). Typically, enterogastric reflux is greatest after Billroth II gastrectomy or gastrojejunostomy, and least after vagotomy and pyloroplasty, with Billroth I gastrectomy giving intermediate values. Patients who are well into the abnormal range of bile reflux may be considered for remedial surgery if symptoms are severe. Remedial surgery will eliminate the bile from the vomitus and may improve the patient’s pain, but it is quite unusual to render these patients completely asymptomatic, especially if they are narcotic dependent.

Bile reflux gastritis after distal gastric resection may be treated by one of the following options: Roux-en-Y gastro jejunostomy; interposition of a 40-cm isoperistaltic jejunal loop between the gastric remnant and the duodenum (Henley loop); Billroth II gastro jejunostomy with Braun enterenterostomy; total gastrectomy with Roux esophagojejunostomy. To avoid bile reflux into the stomach or the esophagus the Roux limb should be at least 45 cm long (preferably 60 cm). The Braun
enteroenterostomy should be placed a similar distance from
the stomach. Excessively long limbs may be associated with
obstruction or malabsorption. All operations can result in mar-
ginal ulceration on the jejunal side of the gastrojejunostomy, and
thus are combined with a generous distal gastrectomy. If this has
already been done at a previous operation, the Roux or Braun
operations may be attractively simple. Whether truncal vagot-
yomy is necessary is controversial in the current era of excellent
acid-suppressing medications. The benefits of decreased acid
secretion following vagotomy may be outweighed by problems
with vagotomy-associated dysmotility in the gastric remnant.
The Roux operation may be associated with an increased risk
of emptying problems compared to the other two options, but
controlled data are lacking. Patients with debilitating bile reflux
after gastrojejunostomy can be considered for simple takedown
of this anastomosis provided that the pyloric channel is open.

Primary bile reflux gastritis (i.e., no previous operation)
is rare, and may be treated with the duodenal switch operation,
especially an end-to-end Roux-en-Y to the proximal duodenum
(see Fig. 26-68). The Achilles’ heel of this operation is, not sur-
prisingly, marginal ulceration. Thus, it should be combined with
highly selective vagotomy, and/or long term acid suppressive
medication.

Roux Syndrome
A subset of patients who have had distal gastrectomy and Roux-
en-Y gastrojejunostomy will have great difficulty with gastric
emptying in the absence of mechanical obstruction. These
patients present with vomiting, epigastric pain, and weight loss.
This clinical scenario has been labeled the Roux syndrome.
Endoscopy may show retained food or bezoars, dilation of the
gastric remnant, and/or dilation of the Roux limb. Anastomotic
inflammation and stricture from marginal ulceration is a con-
 founding finding. An upper GI series confirms these findings
and may show delayed gastric emptying. This is better quanti-
fied by a gastric emptying scan, which always shows delayed solid
emptying, and may show delayed liquid emptying as well.
GI motility testing shows abnormal motility in the Roux
limb, with propulsive activity toward, rather than away from,
the stomach.18 Gastric motility also may be abnormal. Pre-
sumably, the disordered motility in the Roux limb occurs in all
patients with this operation. Why only a subset develops the
Roux syndrome is unclear. Perhaps those patients with disor-
dered gastric motility are at most risk. The disorder seems to
be more common in patients with a generous gastric remnant.
Truncal vagotomy also has been implicated.

Medical treatment consists of promotility agents. Surgi-
cal treatment consists of paring down the gastric remnant. Care
should be taken to preserve adequate blood supply to the new
gastric pouch. If the left gastric artery is intact, a vertically ori-
ented lesser curvature based pouch (similar to gastric bypass)
with excision of the fundus can be considered. If gastric motility
is severely disordered, 95% gastrectomy or total gastrectomy
should be done. The Roux limb should be resected if it is dilated
and flaccid, unless doing so puts the patient at risk for short
bowel problems.

Gallstones
Gallstone formation following gastric surgery generally is
thought to be secondary to vagal denervation of the gallblad-
der with attendant gallbladder dysmotility and stasis. Although
prophylactic cholecystectomy is not justified with most gas-
tric surgery, it should be considered if the gallbladder appears
abnormal, especially if subsequent cholecystectomy is likely to
be difficult. If preoperative evaluation reveals sludge or gall-
stones, or if intraoperative evaluation reveals stones, incidental
cholecystectomy should be considered if it appears straightforward
and the gastric operation has gone well.

Weight Loss
Weight loss is common in patients who have had a vagotomy
and/or gastric resection. The degree of weight loss tends to
parallel the magnitude of the operation. It may be insignificant
in the large person, or devastating in the asthenic female. The
surgeon should always consider the possible nutritional conse-
quences before performing a gastric resection for benign disease
in a thin patient. The causes of weight loss after gastric surgery
generally fall into one of two categories: altered dietary intake
or malabsorption. If a stool stain for fecal fat is negative, it is
likely that decreased caloric intake is the cause. This is the most
common cause of weight loss after gastric surgery, and may be
due to small stomach syndrome, postoperative gastroparesis,
anorexia due to loss of ghrelin, or self-imposed dietary modifi-
cation because of dumping and/or diarrhea. Consultation with
an experienced dietitian may prove invaluable.

Anemia
Iron absorption takes place primarily in the proximal GI tract,
and is facilitated by an acidic environment. Intrinsic factor,
esential for the enteric absorption of vitamin B<sub>12</sub>, is made by
the parietal cells of the stomach. Vitamin B<sub>12</sub> bioavailability also
is facilitated by an acidic environment.

With this as background, it is easy to understand why
patients who have had a gastric operation are at risk for anemia.
Anemia is the most common metabolic side effect in patients
who have had a gastric bypass for morbid obesity. It also occurs
in up to one third of patients who have had a vagotomy and/or
gastric resection. Iron deficiency is the most common cause,
but vitamin B<sub>12</sub> or folate deficiency also occurs, even in patients
who have not had total gastrectomy. Of course, patients who
have had a total gastrectomy will all develop B<sub>12</sub> deficiency
without parenteral vitamin B<sub>12</sub>. Gastric bypass patients should
be given oral iron supplements, and monitored for iron, B<sub>12</sub>, and
folate deficiency. Patients who have had a vagotomy and/or gas-
trectomy should be similarly monitored with periodic determi-
nation of hematocrit, red blood cell indices, iron and transferrin
levels, B<sub>12</sub>, and folate levels. Marginal nutrient status should be
corrected with oral and/or parenteral supplementation.

Bone Disease
Gastric surgery sometimes disturbs calcium and vitamin D
metabolism. Calcium absorption occurs primarily in the duo-
 denenum, which is bypassed with gastrojejunostomy. Fat mal-
absorption may occur because of blind loop syndrome and
bacterial overgrowth, or because of inefficient mixing of food
and digestive enzymes. This can significantly affect the absorp-
tion of vitamin D, a fat-soluble vitamin. Both abnormalities of
calcium and vitamin D metabolism can contribute to metabolic
bone disease in patients following gastric surgery. The problems
usually manifest as pain and/or fractures years after the index
operation. Musculoskeletal symptoms should prompt a study
of bone density. Dietary supplementation of calcium and vitamin
D may be useful in preventing these complications. Routine
skeletal monitoring of patients at high-risk (e.g., elderly males
and females and postmenopausal females) may prove useful
in identifying skeletal deterioration that may be stopped with appropriate treatment.

LAPAROSCOPIC GASTRIC OPERATIONS

The most common laparoscopic gastric operations performed today are for GERD and obesity (see Chapter 27, The Surgical Management of Obesity). However, all of the gastric operations described here can be performed with minimally invasive techniques. Some are technically difficult (e.g., partial or total gastric resection) or are of debatable merit. The operations described in this chapter that lend themselves most readily to minimally invasive techniques are highly selective vagotomy, vagotomy and gastrojejunostomy, and gastrostomy. Laparoscopic wedge resection often is possible for GI stromal tumors, lipomas, or gastric diverticula. Combined endoscopic and laparoscopic techniques occasionally are useful. Robotic gastric operations have been described, but have not yet been widely adopted. Recently laparoscopic resection has been applied increasingly to patients with gastric cancer with promising early results. Advances of laparoscopic instruments particularly energy sources have rendered extended lymph node dissection, including suprapancreatic lymph node dissection feasible. The ratio of D2 lymph node dissection has been increased gradually due to these advances and surgeon’s experiences. Laparoscopy surgery has been widely performed in reconstruction in which the intestine is pulled out of the body through a small laparotomy wound. Recently, based on the improvement in anastomosis devices, pure laparoscopic surgery has also been used in which a series of procedures (lymphadenectomy, resection, and reconstruction) is completely performed intra-abdominally. Finally, diagnostic laparoscopy may prevent a futile laparotomy in some patients with gastric cancer.

While transgastric appendectomy and transgastric pancreatic necrosectomy appears safe and effective in selected patients in experienced centers, the role of transgastric natural orifice endoscopic surgery has yet to be defined.

INTRODUCTION

The surgical treatment of obesity has evolved to focus more specifically on the treatment of medical comorbidities associated with obesity than simply obesity itself. While bariatric surgery remains the overarching name of the field, the importance of treatment of the metabolic aspects of obesity has caused the primary society of surgeons treating these problems to rename the society the American Society for Metabolic and Bariatric Surgery (ASMBS). The nomenclature reflects the new emphasis of treating the metabolic consequences of obesity surgically. For the first time in the history of bariatric surgery, considerable effort is being devoted to scientifically study the physiologic mechanisms that help promote weight loss and, more importantly, resolution of comorbid medical problems associated with obesity.

Other major changes in the field of bariatric surgery in the United States since the last edition of this text include the introduction and rapid adoption worldwide of the laparoscopic sleeve gastrectomy and the simultaneous decreasing popularity of the laparoscopic adjustable gastric banding procedure.

The bariatric surgery community also has focused on improvement of outcomes and treatment for patients. The Centers of Excellence (COE) concept is an obvious example in the United States, but internationally, greater attention to outcomes and optimal results has been uniform. Improved outcomes have been documented in the literature, as have notable prospective randomized trials of medical versus surgical therapy. In the United States, a very recent study has challenged the concept that improved outcomes arise in COEs, citing data that Medicare patients had similar complication rates after surgery before and after the institution of a policy of surgery approval only at COEs.¹

Extension of the indication for metabolic surgery to patients with class 1 obesity (body mass index, 30–35 kg/m²) has been another development during the past few years.² The regulatory and scientific communities have been more willing to acknowledge the efficacy of metabolic surgery for treating comorbid medical problems, such as diabetes, than have the payors. Insurance coverage for appropriately qualified patients remains one of the biggest barriers to the access of appropriate care for patients suffering from morbid obesity.

Acknowledgement of morbid obesity as a disease has recently been adopted by the American Medical Association.³ This comes years after the recognition by the Centers for Medicare and Medicaid Services (CMS) of obesity as a disease,⁴ a reversal of the usual situation in which medical organizations are ahead of payors in recognition of such issues. Despite CMS recognition, regional administrators of CMS still raise unnecessary barriers and make access to care for morbidly obese patients difficult. Long waiting periods, denials for arbitrary issues, and mandatory 6- to 12-month “diet” plans with no requirement for actually losing weight continue to dominate the landscape of the patient seeking metabolic and bariatric surgery. What is also becoming as big an issue for other patients who have had bariatric surgery is denial of subsequent coverage for any emergency complications of the original operation if the patient’s new insurance plan does not cover bariatric surgery. Although the new Affordable Care Act will potentially eliminate the inability to obtain insurance because of pre-existing conditions, there is no guarantee that patients who have had bariatric surgery will be afforded the same rights to payment for emergent and needed surgery should a subsequent complication arise.
Key Points

1. Surgical therapy is the only effective and proven therapy for patients with severe obesity (body mass index >40 kg/m²). Bariatric operations prolong survival and resolve comorbid medical conditions associated with severe obesity.

2. During the years 1999 to 2003, called the Bariatric Revolution in the United States, the availability of a laparoscopic approach for bariatric operations caused major changes in the field, including a massive increase in the number of procedures performed as well as an increased public and professional awareness and understanding of the field.

3. Bariatric operations involve either restriction of caloric intake or malabsorption of nutrients, or both. Long-term follow-up is essential before the merits of an operation can be confirmed.

4. Patients who develop a bowel obstruction after laparoscopic gastric bypass require surgical and not conservative therapy due to the high incidence of internal hernias and the potential for bowel infarction.

5. Malabsorptive operations are highly effective in producing durable weight loss but have considerable nutritional side effects. Patients undergoing such procedures require complete follow-up and must take appropriate nutritional supplements.

6. The Roux-en-Y gastric bypass is the most commonly performed bariatric procedure, whereas the sleeve gastrectomy is the most rapidly increasing procedure worldwide.

7. All bariatric operations are tools that serve to allow the patient to lose weight, become healthier, and improve their quality of life. These changes are only maintained long-term if the patient permanently adopts the new eating patterns and exercise habits that are taught and expected in the early year(s) after surgery.

8. Bariatric surgery is also metabolic surgery, treating the varied metabolic consequences of the comorbid diseases arising from severe obesity. Some operations are particularly effective treatments for such metabolic consequences, such as gastric bypass for type 2 diabetes.

The merger of the COE systems of the ASMBS and the American College of Surgeons (ACS) has been a major positive event in recent years as well. Thanks to the leadership of Robin Blackwell, M.D., ASMBS President from 2011 to 2012, supported by the ASMBS Executive Council, the ASMBS took the initiative to merge with the ACS to create a single uniform system acceptable to both groups and clearly more authoritative due to its singular position. The ACS, to its credit, provided large fiscal and human resources to support the merger and adoption of a single COE system. Since the merger, the incorporation of virtually all the centers in the two systems has occurred under one new system. Outcomes, as reported for review by the oversight committee, are better than ever. Our patients have thus been well served.

THE DISEASE OF OBESITY

Obesity is the second leading cause of preventable death in the United States, currently outdone only by smoking. However, obesity as a separate disease entity is still underappreciated and certainly misunderstood. The fact that the American Medical Association waited until the summer of 2013 to acknowledge obesity as a disease entity illustrates this statement.

Obesity is a disease and is likely multifactorial in its origin. We may come to a simpler and direct understanding of its pathogenesis in the future with increased understanding of molecular genetics, but for now, it remains a complex issue. The components of the disease likely include a combination of environmental and genetic factors. The recent rapid rise in the incidence of obesity in less than a generational time suggests that genetic etiologies alone cannot be responsible for the disease. Nevertheless, the numerous factors contributing to the disease increase the difficulty in understanding its causes.

The degrees of obesity are defined by body mass index (BMI = weight [kg]/height [m²]), which correlates body weight with height. Controversy exists as to the most accurate system by which to classify obesity. BMI has its inaccuracies, especially for the heavily muscled individual who may weigh more but have a low amount of body fat. However, BMI is the clinically easiest system to use, employing the simply measured parameters of height and weight. The World Health Organization classification of obesity is given in Table 27-1. It should be noted that for Asian populations, classifications remain the same as the international classification, but the public health action points for interventions are set at 23, 27.5, 32.5, and 37.5 kg/m².

Prevalence and Contributing Factors

Severe obesity is reaching epidemic proportions in the United States and dramatically increasing throughout the rest of the world. Since 1960, surveys of the prevalence of obesity have been conducted every decade by the National Center for Health Statistics. Data on obesity statistics have been updated annually since 1985. The latest figures for obesity incidence in the United States are that 35.7% of U.S. adults are obese (class 1 or higher).8

Genetic and environmental factors contribute to the development of obesity. While children of parents of normal weight have a 10% chance of becoming obese, the children of two obese parents have an 80% to 90% chance of developing obesity by adulthood. The weight of adopted children correlates strongly with the weight of their birth parents. Furthermore, concordance rates for obesity in monozygotic twins are doubled compared to others.6 Diet and culture are important factors as well; these environmental factors contribute significantly to the epidemic of obesity in the United States since the rapid increase in obesity during the past two decades cannot be explained by any genetic etiology.

Other factors appear to contribute significantly to severe obesity. Intermittent or consistent excessive caloric intake occurs. The lack of satiety, on a consistent or intermittent basis, appears to be strongly correlated to such episodes of excessive caloric ingestion. As yet, the physiologic basis for the explanation of such lack of satiety is not understood. Other factors commonly suggested to play a role in the disease of obesity include decreased energy expenditure from reduced metabolic activity, reduction in the thermogenic response to meals, an abnormally high set-point for body weight, or a decrease in the loss of heat energy. Another factor that may influence absorption of ingested food is intraluminal bacterial composition of the intestinal tract. Studies have documented a difference in the composition of the intestinal flora of obese versus normal-weight individuals.7

Obese individuals have excessive adipose cells, both in size and number. The number of such cells often is determined early in life; adult-onset obesity is largely a product of increase in adipose cell size. Weight gain results from increase in both adipose cell size and number. Adipose tissue may be deposited in large quantities in the subcutaneous layer of the abdominal wall or the viscera. Males tend to have central visceral fat distribution, whereas females more often have a peripheral or gluteal fat distribution. Central or visceral fat distribution is associated with metabolic diseases such as diabetes, hypertension, and the metabolic syndrome.8

Concurrent Medical and Social Problems

The severely obese patient often presents with chronic weight-related problems, detailed below. However, the single most difficult aspect of the disease of severe obesity for those suffering from it is the discrimination they face from the rest of the population with respect to social stigmatization. This prejudice against obesity remains the last unlegislated discrimination in existence. Obese individuals are routinely discriminated against in terms of employment. Public facilities often do not allow them to participate in activities. Examples include the size of airline seats and bathrooms, the availability of appropriate clothing options, and the size of automobile cabins. Severely obese individuals are thought of by much of the public as being lazy or gluttonous and lacking self-discipline. They often endure not only discrimination and prejudice, but outright ridicule and disrespect. Consequently, the stigma of severe obesity has a major impact on social function and emotional well-being. Thus, psychological disorders such as depression are found in an extraordinarily high incidence in this population versus the general public. Poor self-image is almost universal among obese individuals.

Significant comorbidities, defined as medical problems associated with or caused by obesity, are numerous. The most prevalent and acknowledged of these include degenerative joint disease, low back pain, hypertension, obstructive sleep apnea, gastroesophageal reflux disease (GERD), cholelithiasis, type 2 diabetes, hyperlipidemia, hypercholesterolemia, asthma, hypoventilation syndrome of obesity, fatal cardiac arrhythmias, right-sided heart failure, migraine headaches, pseudotumor cerebri, venous stasis ulcers, deep venous thrombosis, fungal skin rashes, skin abscesses, stress urinary incontinence, infertility, dysmenorrhea, depression, abdominal wall hernias, and an increased incidence of various cancers such as those of the uterus, breast, colon, and prostate.9

Prognosis

Obesity has a profound effect on overall health and life expectancy, largely secondary to weight-related comorbidities. It is estimated that a severely obese male at age 21 will live 12 years less and a woman 9 years less than a nonobese individual. The incidence of severe obesity in the population is comparable for females below and above the age of 50 years, whereas for men, it is decreased above age 50. This is due to the fact that the severely obese man often is dead of comorbid medical conditions, especially cardiac arrhythmias and coronary artery disease, by age 50. A study carried out by the Veterans Administration showed a 12-fold increase in mortality among 200 morbidly obese men age 25 to 34 years and a six-fold increase in mortality among those age 35 to 44 years over a 7-year follow-up period.10 Decreased quality of life also results due to severe obesity. Most patients seeking surgical treatment of severe obesity do so because of the medical issues they face from comorbid conditions or the decreased quality of life they are experiencing as a result of severe obesity. Bariatric surgery can significantly prolong the lifespan of a severely obese individual, as well as improve the quality of that life.

Medical Management

Medical treatment for severe obesity is aimed at reducing body weight with a combination of decreased caloric intake and accompanying increases in energy expended from moderate exercise. This method of weight loss is the safest possible and may work well for obese individuals who have modest amounts of weight to lose to regain normal body weight or return to being simply overweight instead of obese. However, for the severely obese individual, who usually must lose at least 75 or more pounds to achieve elimination of obesity, this daunting task is extremely difficult. The success rate for the severely obese patient population that tries dieting and exercise as a means of losing enough weight to no longer be obese and maintaining that weight loss is only approximately 3%.

Although the success rate is limited with diet and exercise alone, all severely obese individuals are asked to attempt this route of weight loss prior to undertaking any surgical therapy.
There are two main reasons for this. The first is to allow those who can achieve such weight loss through the safest possible means to do so. The second, and by far the most practical, is to have the severely obese individual begin to appreciate and practice the lifestyle changes that must ultimately become routine for them once weight loss is achieved, by whatever means. Thus the dieting and exercise of conservative weight loss plans are important preparation for the incorporation of such habits into the patient’s lifestyle postoperatively after bariatric surgery. The adjustment of the patient’s lifestyle to include these measures is the key to long-term success with any bariatric operation. Failure to do so usually results in regain of weight and sacrifice of any health benefits initially gained by the immediate postoperative weight loss.

The treatment of severe obesity should be initiated with simple lifestyle changes, including moderate reduction of caloric intake and beginning an exercise plan. Walking is the most common choice for this patient population, who may be unable to perform extremely vigorous exercise initially. Medical comorbidities must be identified and treated. Usually the patient’s primary care physician will have already accomplished this, but we do at times identify bariatric-related comorbidities on initial history and physical examination in our clinic.

The severely obese patient will usually have been given dietary counseling by his or her primary care physician and often placed on a medically supervised diet. Most patients also have attempted commercially sponsored diets and diet plans. Success following these is not uncommon, but sustained weight loss for more than a year after stopping the program is uncommon. While primary care physicians usually do an outstanding job of identifying and treating comorbid medical problems, their offices usually do not have the related support staff in terms of nutritionists and psychologists, who are often very helpful in providing services to the severely obese patient undergoing significant lifestyle changes.

Lifestyle changes of diet, exercise, and behavior modification constitute the first tier of therapy for obesity. Dietary restriction and exercise can each independently create a caloric deficit. A daily energy deficit of 500 kcal/d, resulting in a weekly deficit of 3500 kcal, results in the loss of 1 lb of fat weekly. It has been shown that low-calorie diets (800–1500 kcal/d) are as effective as very-low-calorie diets at 1 year, but result in a lower rate of nutritional deficiencies. Such diets may produce an average of 8% body weight loss over a 6-month period. Longer follow-up shows recidivism. Physical activity of a moderate daily nature can produce a 2% to 3% body weight loss.

A behavioral modification program, which provides desirable rewards for meeting short-term dietary or exercise requirements, was shown in combination with diet and exercise to produce as much as a 10% weight loss at 6 months in one study. This weight loss was only sustained in 60% of patients at 40 weeks, and at 1 year, the average sustained weight loss was decreased to 8.6%. Dietary, exercise, or behavior modification therapy is appropriate treatment for patients who are overweight (BMI <30 kg/m²) and highly recommended for patients with a BMI between 30 and 35 kg/m². Most of the studies looking at dietary therapy do not include a patient population that is largely obese (BMI >30 kg/m²). Dietary therapy can be effective in producing improvements in comorbid conditions such as diabetes mellitus, with weight loss of 2.3% to 3.7% influencing the disease.

Thus, lifestyle changes can be effective in improving the health of the nonobese, but less so for the obese population.

Pharmacologic therapy is also an option for patients attempting to lose weight. Unfortunately, the number of effective pharmacologic agents is small compared to the number of products sold with allegations that they will promote or support weight loss. Pharmacotherapy is normally used only after lifestyle changes and dietary therapies have failed. It is used either as primary therapy alone or in conjunction with simultaneous diet and exercise therapy.

Orlistat inhibits gastric and pancreatic lipase enzymes that promote lipid absorption in the intestine. It produces a weight loss of between 6% and 10% of body weight after 1 year, but cessation of the drug usually results in prompt regain of lost weight. Pharmacotherapy is recommended as an adjunctive or supplementary therapy to lifestyle changes including diet and exercise or behavioral therapy by the National Institutes of Health (NIH) consensus guidelines for treatment of obesity. Two new medications have been approved by the Food and Drug Administration (FDA) within the past few years for weight loss. Qsymia, a combination of phentermine and topiramate, produced a 5% weight loss in over 70% of patients after 1 year. Lorcaserin (Belviq), a central serotonin agonist, produced a 5% weight loss in 47% of patients taking the medication.

Since medical therapies are almost uniformly ineffective long-term for patients with severe obesity, the severely obese patient tends to continue to gain weight over time. The number and strength of prescribed medications slowly increase as the medical comorbidities become increasingly worse. Unfortunately, for the majority of severely obese patients, this process continues unabated until death results eventually from the comorbidities. Until recently, less than 1% of severely obese patients underwent surgical treatment for obesity annually. That number has now increased, but still is not over 2% of individuals. Even accounting for patients referred for surgery and felt to be poor candidates, it is likely that less than 5% of patients with severe obesity are referred on an annual basis.

Part of this issue may be patient aversion to surgical therapy. Primary care physician awareness, patient reticence, and economic concerns about potentially losing employment due to time off required for surgery or its complications have been the primary reasons cited for the lack of increased performance of bariatric and metabolic surgery. Lack of insurance coverage by many patients is also a primary reason for not seeking surgical therapy for the medical problems associated with severe obesity. Disincentives posed by insurance companies, such as required dietary periods that clearly have no scientific or clinical basis of merit, are still used to discourage patients from pursuing surgical therapy. The lack of efficacy and potential harm to patients of such policies has been clearly demonstrated in the literature.

**OVERVIEW OF BARIATRIC SURGERY**

Bariatric operations produce weight loss through at least two mechanisms and probably many more that are not known. The most common is restriction of intake. Malabsorption of ingested food is the second mechanism. Restrictive operations may include no or only a modest malabsorptive component. Malabsorptive operations may have some restrictive component, but it is secondary to the malabsorptive aspect of the operation.
Table 27-2 describes the common currently performed operations listed by mechanism of action.

Evolution of Bariatric Surgery

During the 1950s, operations were first performed to treat severe hyperlipidemia with associated obesity.24 These were ileocolic bypass operations to limit absorption and were associated with severe nutritional complications and liver failure postoperatively. The jejunoileal bypass was then devised and popularized in the mid-1970s.25 It was also a malabsorptive operation, but bypassed only a portion of the small intestine. Complications after this procedure included severe diarrhea, electrolyte disturbances, protein-calorie malnutrition, renal stones, and liver failure.

In 1969, Mason and Ito performed the first gastric bypass, describing a loop of jejunum connected to a transverse proximal gastric pouch.26 Bile reflux esophagitis was severe postoperatively, causing Griffin and colleagues to describe the Roux-en-Y modification of the gastric bypass in 1977.27 The gastric pouch was altered from transverse to vertical using the upper lesser curvature as well.

During the 1970s, the dismal failure of the jejunoileal bypass resulted in a very bad reputation in general for bariatric surgery among general surgeons who had performed the procedure or cared for patients suffering from its complications. The reputation was not enhanced by the many variations of gastric stapling that then became common during the 1970s and early 1980s. Such operations often consisted of a few rows of staples partially across the upper stomach for restrictive purposes. Since the procedure was easily done, some surgeons performed it in prolific numbers. Staple breakdown predictably occurred months to years later, with subsequent weight regain. These procedures added to the string of failures of bariatric operations.28

In 1980, Mason29 first performed the VBG, which was a restrictive procedure using a stapled proximal gastric pouch of the upper lesser curvature of the stomach with a restrictive band for its outlet to the rest of the stomach. This operation produced excellent initial weight loss (50% of excess weight or more) with low morbidity and mortality. It rapidly became the most commonly performed bariatric operation in the United States during the 1980s. However, by the early 1990s, it became clear that patients who underwent VBG tended to adopt a diet of high-calorie liquids and regained weight.30 A significant incidence of stenosis at the band was also a problem.31 Long-term weight loss was poor,32 and by the 1990s in the United States, Roux-en-Y gastric bypass (RYGB) became the procedure of choice for bariatric surgery.

In Italy, in the meantime, Scopinaro had developed and popularized the biliopancreatic diversion (BPD) in the early 1980s.33 This procedure, described in more detail later, has been, along with its modification to include duodenal switch (DS),34 the only major malabsorptive operation to enjoy long-term success. BPD and DS are both still used by a fairly select few surgeons throughout the world and have traditionally represented and continue to represent less than 5% of operations performed in the United States.

Fixed banding of the stomach, besides the VBG, was also described by other surgeons in the 1980s and 1990s. Kuzmak is credited with describing the fixed gastric band procedure, which later led to the development of the adjustable gastric banding operation.34

The laparoscopic alternative to bariatric surgery became available in the 1990s. Belachew performed the first laparoscopic adjustable gastric banding (LAGB) operation in 1994.35 Wittgrove and Clark performed the first laparoscopic RYGB the same year.36 Since the former operation is technically much easier than the latter, it was not surprising that it became very popular and frequently performed in Europe and Australia during the late 1990s. In 2001, LAGB was approved for use in the United States. Its popularity increased annually until 2009, but since then, it has decreased in popularity. Sleeve gastrectomy (SG) has enjoyed a rapid increase in popularity both in the United States and internationally since 2008. Buchwald and Oien37 have recently described the international trends in the performance of bariatric operations.

The Bariatric Revolution

The Bariatric Revolution is a term applied to the 5-year stretch from 1998 to 2003 during which the number of gastric bypass operations performed in the United States, membership in ASMBS, and public recognition and interest and professional respect for the field dramatically increased. Few medical centers in the United States offered a laparoscopic approach to bariatric surgery prior to 1998. Several centers, most notably Schauer and colleagues at Pittsburgh, then began numerous programs to teach many bariatric surgeons the procedure. Simultaneous improvement in the laparoscopic instruments for bariatric procedures combined with these programs to allow the performance of laparoscopic Roux-en-Y gastric bypass (LRYGB) in numerous centers over the next few years. The field then literally exploded in terms of growth in the United States. Figure 27-1 illustrates the volume of LRYGBs performed during the years prior to and during the Bariatric Revolution. Operative procedures increased nearly eight-fold. Membership in the American Society for Bariatric Surgery (the name of the ASMBS at that time) tripled during these years. The number of minimally invasive fellowships offered to graduating residents, most of whom included bariatric surgical procedures as a major component of the case load, increased from about 25 to 125 during these years.
Public recognition of the procedure markedly increased due to public figures in the media undergoing bariatric surgery. The widespread availability of the Internet to prospective patients allowed much more information to be relayed. Patients who had or were contemplating surgery were able to communicate via the Internet. Videos of bariatric operations became available via several media outlets including television and the Internet. Many U.S. surgical departments that had previously shunned the field of bariatric surgery recruited bariatric surgeons and established programs. Hospitals without programs recruited surgeons so they could offer the service. Bariatric surgery presentations at national surgical meetings became common instead of rare.

Indications

The indications for performing bariatric surgery remain as described in the NIH Consensus Conference of 1991. The only major difference is the procedures that are now recognized as standard procedures. These were defined by the CMS in 2005 as those listed in Table 27-2, with the exception of SG. SG did not receive approval until 2012, when after a controversial initial rejection of coverage, the CMS decided to allow coverage based on the discretion of regional carriers. The standard and somewhat conservative indications for performing bariatric surgery are summarized in Table 27-3.

Contraindications

Of all the reasons a patient who desires bariatric surgery cannot have an operation, insurance coverage, or lack thereof, is the most common reason. This factor, however, is normally beyond surgeon control. Assuming the patient does have coverage or financial means to qualify for surgery, then application of the NIH criteria is the next consideration. Once a patient qualifies according to those criteria, then consideration of medical, social, and psychological issues can determine reasons to avoid surgical therapy.

The NIH criteria do not set limits for age, and surgeon opinion on this issue varies widely. Surgeons have variable practice patterns as to performance of surgery in the older patient. The philosophy for age restriction is two-fold: A large number of younger patients are interested in and eligible for bariatric surgery, and there is a greater likelihood that a longer period of postoperative benefit in terms of improved quality of life and longevity will occur with a younger patient population. Alternatively, older patients are more likely to have debilitating comorbid conditions and thus have immediate benefit in quality of life but not necessarily enhanced longevity.

Medical issues that preclude patients from being good surgical candidates include American Society of Anesthesiologists class IV disease of a nature that makes surgical therapy extraordinarily high risk. Psychological instability or the inability to understand the implications of the proposed operation and what changes will result from it in terms of the patient’s lifestyle are also contraindications. Known and documented drug or alcohol addiction is a contraindication to surgery. Smoking is a relative contraindication, and requirement of cessation of smoking varies by surgical practice. A poorly controlled eating disorder, especially bulimia, is also a contraindication to surgery. Nonambulatory status is a relative contraindication to surgery, especially if the obesity is so severe that the patient cannot normally do self-care or would not likely be able to do so after surgery. Such patients have excessive morbidity in our experience, and placement in care facilities postoperatively after recovery from surgery is often impossible due to their size and limitations of physical ability. Although hard to determine on a single visit, an accumulation of evidence that suggests the patient views the operation as a “magic bullet” for which they must only show up and after which they will not be required to make any substantive changes in eating or lifestyle is a potential valid reason to deny surgery. Finally, lack of sufficient social support, an extremely poor or unsupportive home environment, or hostile spouse or relatives can be contraindications to surgical care, since such supportive environmental factors are important to optimize outcomes once discharged from the hospital. Table 27-4 summarizes potential contraindications for surgery.

PREOPERATIVE ISSUES

Patient Selection

Patient selection for surgery should be based on a multidisciplinary team evaluation. The patient has usually been screened by his or her primary care physician prior to referral, with major medical issues addressed prior to referral. Qualification by NIH criteria and availability of insurance coverage can be handled by office administrators to document and confirm prior to the first appointment.

The preoperative assessment of the patient for bariatric surgery must include input from the nutritionist as an important independent evaluation. Careful assessment of the patient’s eating habits, knowledge, self-awareness, and insight is important. An estimation of the patient’s motivation to change eating habits is important. The nutritionist should have at least one assessment session with the patient and an educational session preoperatively once the decision to proceed with surgery has been determined. The operation to be performed requires specific nutritional counseling and education.

Psychological assessment is required by most insurance carriers. One major benefit of the psychological assessment is to determine the patient’s understanding of the operation and whether he or she has a realistic understanding of the changes that are needed in lifestyle for optimal outcomes. The psychologist or psychiatrist often may diagnose previously unappreciated depression, which is prevalent in nearly 40% of our preoperative patients when carefully screened. Its treatment is felt to improve postoperative outcomes.

Most of the patients referred for surgery who have been screened for qualification by NIH standards will be appropriate candidates for bariatric surgery. Some will decide against the procedure after thorough educational and counseling sessions. Such sessions are imperative for improving outcomes. Providing both written detailed information and a verbal presentation by the multidisciplinary team to educate patients preoperatively regarding bariatric surgical procedures and expected outcomes and potential complications is recommended. Informed and prepared patients will likely be much more compliant with perioperative and postoperative requested behavioral and eating changes. Some patients who decide against the procedure will return in the future after their obesity comorbidities worsen. Reevaluation for continued appropriateness as a good surgical candidate is equally indicated at such time.

Preoperative Preparation

Preoperatively, current comorbid and other medical problems and their optimal therapy are confirmed. Potentially undiagnosed medical problems are sought. Screening for “hidden” diseases such as coronary artery disease in those patients over age 50 is important. For such patients, or those with known cardiovascular disease, a preoperative cardiology consultation is recommended. Such consultation usually then involves electrocardiogram (ECG), echocardiogram, and stress test, with the results of these at times suggesting need for cardiac catheterization. Another condition often underdiagnosed preoperatively in the severely obese patient population is obstructive sleep apnea (OSA). The Epworth Sleepiness Scale, a standard set of questions evaluating daytime sleepiness, is often used as a screening tool for OSA. Many institutions are routinely employing it for all surgical patients, given the recognition that OSA increases postoperative morbidity after all operations. Patients who give a history of loud snoring, morning tiredness on waking, and falling asleep easily while driving or sitting likely have OSA. A diagnostic sleep study is indicated for these individuals. One report suggests that the incidence of sleep apnea in severely obese patients, when all are routinely subjected to sleep studies, may approach 80%. Once diagnosed with sleep apnea, patients should use their positive airway pressure appliance as treatment. Use of this system in the immediate postoperative period is especially important to prevent episodes of hypoxia and potentially resulting cardiac arrhythmias. Asthma and hypoventilation syndrome of obesity are other significant pulmonary diseases often requiring preoperative management. Hypoventilation syndrome of obesity is defined as resting arterial partial pressure of oxygen less than 55 mmHg and partial pressure of carbon dioxide greater than 47 mmHg, with accompanying pulmonary hypertension and polycythemia. Pulmonary consultation is indicated for patients with hypoventilation syndrome. Postoperative intensive care unit hospitalization, rarely used after bariatric surgery, may be indicated for these patients.

For patients with active GERD on medication, a preoperative screening upper endoscopy to rule out Barrett’s esophagus and to rule out intrinsic lesions of the stomach or duodenum is recommended. This is especially true for patients planning LRYGB, where the distal stomach and duodenum will be excluded from easy inspection postoperatively. Several studies have documented the considerable incidence of preoperative pathology on flexible upper endoscopy for this patient population, as well as a small but not insignificant incidence of pathology resulting in alteration of the originally planned surgical procedure. At Virginia, our experience was that such pathology was present in 4.6% of examinations. The presence of a hiatal hernia detected on preoperative esophagogastroduodenoscopy will alert the surgeon for the need to perform intraoperative repair.

Patients who are on anticoagulation medication for prosthetic cardiac valves or history of recent venous thromboembolism must have their anticoagulation managed perioperatively. Options include total cessation of oral warfarin therapy 5 days prior to surgery, bridging this time with subcutaneous low-molecular-weight heparin, or, more rarely, preoperative admission for intravenous heparin anticoagulation, which is then stopped 6 hours prior to surgery.

Patients with a strong history of previous venous thromboembolism or who are felt to have multiple risk factors for postoperative venous thromboembolism are potential candidates for preoperative placement of a temporary inferior vena cava filter. Such filters are placed the day prior to surgery by our interventional radiology colleagues and removed 3 to 6 weeks postoperatively. However, a report on a large experience of collected hospitals has shown this procedure has potential complications and morbidity, which may outweigh its use in all but the most high-risk patients.

Some surgeons routinely perform screening ultrasound of the abdomen for patients planning to undergo LRYGB with an intact gallbladder to rule out the potential presence of gallstones. Should gallstones be discovered, simultaneous laparoscopic cholecystectomy is one option, whereas deferring until after weight loss is another reasonable option. Recent analysis of our experience with simultaneous cholecystectomy at the University of Virginia has shown the average increase in operative time to be approximately 30 minutes for both LRYGB and RYGB with no increase in hospitalization or morbidity. An earlier study at
Pittsburgh did demonstrate an increased length of hospitalization for patients having simultaneous cholecystectomy. When a patient does not have gallstones on preoperative ultrasound, use of prophylactic ursodiol in a dose of 300 mg twice a day will decrease the incidence of gallstone formation after RYGB to approximately 4%. Controversy currently exists as to the proper role of simultaneous laparoscopic cholecystectomy at the time of LAGB. The conservative approach is to not perform such an operation, given the small potential for gallbladder bile spillage resulting in an infection of the prosthesis. However, some reports have shown that this risk may be very low. Another value of a preoperative ultrasound of the abdomen is the assessment of liver size and composition. An ultrasound that reveals a large fatty liver in a patient planning to undergo either LAGB or LRYGB should alert the surgeon to the high potential for technical difficulty in liver retraction and exposure. We have converted to an open incision and even deferred proceeding with the operation altogether when confronted with an excessively large or a tremendously large liver, respectively. Knowledge of this prior to surgery allows the patient to follow a low-calorie diet to shrink the liver preoperatively.

Some surgeons require patients to follow a low-calorie diet in the immediate preoperative period, requiring weight loss prior to proceeding with surgery. Some data exist indicating that preoperative weight loss by patients may improve outcomes. Such studies suffer from the fact that the patients who are most compliant and lose weight preoperatively may be the most compliant postoperatively, accounting for the improved outcomes. Preoperative weight loss is not necessary to achieve good outcomes from surgery. Requiring preoperative weight loss raises the dilemma of whether patients who do not achieve weight loss should be then denied the benefit of surgical therapy.

Another controversial area is the requirement for cessation of smoking by patients prior to undergoing surgery. Some surgeons make this an absolute requirement, while others do not. Certainly the risk of marginal ulcer after RYGB, which is more difficult to treat and has a higher recurrence rate in smokers, should be considered as a factor in whether to offer the smoking patient this operation.

Other preparation for bariatric surgery includes the performance of a baseline arterial blood gas measurement. This is especially important in any patients with significant pulmonary disease or hypoventilation syndrome of obesity, since a baseline value of “normal” for the patient must be appreciated if ventilator management postoperatively is necessary.

Baseline evaluation of thyroid function is indicated preoperatively, since hypothyroidism is not uncommon in this patient population. Serum chemistries, liver function tests, and usual screening blood tests are done. Blood tests to determine baseline nutritional parameters are not uncommonly abnormal for low iron and vitamin D levels. The former finding is common in the menstruating female population, obese or not, while the latter has been reported for the population in general but especially for the obese patient population. The necessity to treat low vitamin D levels preoperatively is unclear in terms of its influence on clinical outcomes. However, the primary reason to correct low vitamin D is improved long-term bone disease health.

Preoperative education is important to reemphasize important points of likely events of the perioperative period, expected postoperative course, and instructions for postoperative activity and diet. Expectations for patients include ambulation on the day of surgery, following postoperative dietary instructions, taking recommended vitamin and mineral supplements, and following a regular exercise plan.

**Anesthesiology Issues**

A preoperative anesthesiology assessment is indicated for all patients undergoing bariatric surgery. This assessment confirms the optimal assessment and management of ongoing comorbid medical problems. It also includes the aforementioned cardio-pulmonary evaluation to determine any underlying pathology that requires preoperative treatment to decrease perioperative morbidity from cardiopulmonary complications.

It is important that the anesthesiologist be experienced in performing general anesthesia management for the bariatric patient. There is no question that the consistent participation of a few selected and experienced anesthesiologists who specialize in the care of the bariatric patient will minimize morbidity of surgical outcomes. Perioperative and intraoperative communication between the anesthesiology team and the surgical team is particularly important during bariatric operations to facilitate the smooth flow of the operation and avoid complications from the procedure.

Two major difficulties that the anesthesiologist faces when performing a general anesthetic for the severely obese patient are vascular access and airway management. Both are significantly more difficult in the obese patient population than the normal-weight population. Central venous access is at times the only available route for establishment of a reliable intravenous access. Access to both arms during the procedure is standard in our operating rooms; this allows for additional larger bore intravenous access should an episode of intra-abdominal hemorrhage occur. Jugular cannulation is often very difficult due to neck adipose tissue. However, ultrasound guidance can facilitate this procedure. Subclavian access is performed when other central access routes are not feasible.

Management of the severely obese patient airway is often a major challenge for the anesthesiologist and must be done well to avoid potentially significant morbidity. Videotelescopic intubation systems are successfully used in some institutions to manage difficult airway intubation. Fiberoptic laryngoscopy is more commonly used for the difficult airway should standard laryngoscopy provide an inadequate view. For the most difficult class IV or even class III airways, a fiberoptic guided intubation is used. Experience is key in performing smooth intubation of this patient population. Significant preoxygenation for 3 minutes or longer prior to intubation is used for the severely obese patient to provide a longer safe duration for intubation should difficulties be encountered. However, desaturation must be immediately addressed with reestablishment of oxygenated ventilation because this patient group does not tolerate any prolonged desaturation without potential adverse cardiopulmonary consequences.

The anesthesiologist must be adept at understanding and managing alterations in cardiopulmonary function from the use of a pneumoperitoneum during laparoscopic bariatric procedures. These alterations include the effects of carbon dioxide absorption on required minute ventilation, the potential for bradycardia, and the potential for decreased systemic pH with longer procedures in patients with preexisting cardiopulmonary disease. Arterial monitoring of the latter group of patients may be necessary by the anesthesiology team, and a radial arterial line is standard for such patients.
Drug pharmacokinetics differ in severely obese patients as well. Changes in volume of distribution include smaller-than-normal fraction of total body water, greater adipose tissue content, altered protein binding, and increased blood volume. Possible changes in renal function and hepatic function must be considered when administering drugs.

Specific anesthetic drug metabolic alterations in the severely obese include a larger volume distribution of thiopentone, resulting in a prolonged effect of the drug.

Calculation of the dosage should be done by lean body weight. Benzodiazepines also exhibit a prolonged elimination phase, causing persistence of their effects. Increased pseudocholinesterase activity is present in the severely obese patient, requiring increased dosages of pancuronium. Enflurane metabolism is increased over the average-sized person, requiring a lower dosage of this agent.

**BARIATRIC SURGICAL PROCEDURES**

**Laparoscopic versus Open Procedures**

The procedures in this section will be described using a laparoscopic approach as the default or typical approach. RYGB, BPD, and DS may still be performed by some surgeons using an open approach, but this has now become the exception. Minimization of the morbidity of the open incision, especially incisional hernias and wound complications, as well as earlier hospital discharge and lower 30-day complication rates have all been clearly shown to favor using a laparoscopic approach when feasible. In addition, the logical assumption that avoiding the major tissue trauma associated with a lengthy abdominal wall incision is beneficial to patient recovery has been confirmed. Most importantly, patient interest in bariatric surgery increased dramatically once a laparoscopic approach was available for these procedures, especially RYGB. In the twenty-first century, most prospective bariatric patients are informed enough about the options for surgery that they seek out a surgeon who does laparoscopic bariatric surgery.

When an open surgical approach is used for any of these procedures, an upper midline incision is the most commonly used approach. Some surgeons have had excellent success with a left subcostal incision for performing RYGB. Mechanical retractors afford additional exposure for open surgery and are indicated. Wound closure for midline incisions usually is performed using heavy monofilament suture for the midline fascia, even if conversion to an open approach occurs. Instrumentation for performing laparoscopic bariatric surgery has dramatically improved in the past 15 years and continues to improve. We now favor using certain laparoscopic instruments, such as the staplers and harmonic scalpel, even if conversion to an open approach occurs.

Conversion to an open incision is appropriate in circumstances where patient safety would potentially be compromised by persisting with a laparoscopic approach. Table 27-5 lists appropriate reasons for conversion to an open incision as well as consideration for beginning with open surgery if certain conditions are known, such as an existing large upper abdominal incisional hernia or known severe intra-abdominal adhesions. Conversion to an open incision should not be viewed as a failure by the surgeon, nor should such an attitude bias the surgeon in favor of persisting with a laparoscopic approach if the operation is not progressing or if a complication is worsening when it could be corrected more quickly using an open approach. Patient safety is the gold standard for determining the timing and appropriateness of conversion. Usually, if conversion is needed, it is best to do so as early in the course of the operation as possible.

**Postoperative Follow-Up**

Short-term follow-up is defined as follow-up of up to 2 years. Unfortunately, even in the best of practices in the United States, because of the lack of a centralized health system or registry, 1-year follow-up of 90% or greater is a laudable achievement and rarely reported in most case series. Recommendations for bariatric centers wishing to be COEs are that 75% of patients are followed for 5 years with restrictive operations, and 90% are followed if they have malabsorptive operations. Those recommendations, however, are based on having a system that is best to do so as early in the course of the operation as possible.

The goals of short-term follow-up are to maximize care of the patient in the postoperative period; assist in adjustment to

---

**Table 27-5**

**Indications for conversion from laparoscopic to open surgery**

1. Failure to establish an adequate pneumoperitoneum
2. Hemodynamic adverse reaction to pneumoperitoneum
3. Intra-abdominal adhesions precluding safe access or presenting excessive difficulty to access abdomen
4. Hepatomegaly such that retraction is not feasible or, even with retraction, organ visualization is obscured
5. Intraoperative complications such as hemorrhage that are best managed with an open approach
6. Exceedingly thick body wall precluding adequate trocar access or manipulation
7. Existing large upper abdominal wall hernia that optimally can be repaired simultaneously using the same incision

---
new eating, exercise, and lifestyle patterns; be on the alert for and treat postoperative complications; and recommend measures to limit such complications. Objective data that should be obtained after all bariatric operations include weight loss, change in BMI, resolution or improvement in medical comorbidities, and any adverse events or complications that occur. Optimally, assessment of quality of life can help gauge efficacy as well, with the Short Form-36 (SF36) questionnaire being one standard, frequently used example. Short-term follow-up data do give a good reflection of the safety of the procedure, but only an estimate of the efficacy regarding weight loss and effect on resolution of medical comorbidities.

Medium-term follow-up is defined as that from 2 to 5 years. Medium- and long-term follow-up, defined as greater than 5 years, are the only means by which the true long-term efficacy of bariatric surgical operations can be assessed. Operations that initially appear quite promising, such as the VBG or even the jejunoileal bypass, were shown with long- and medium-term follow-up, respectively, to have significant deficiencies in efficacy for the VBG and safety for the jejunoileal bypass. Other stapled gastroplasties similarly did not demonstrate efficacy on medium-term follow-up.

Unfortunately, to date, there has been no conventional method of reporting outcomes after bariatric surgery. The ideal publication includes quantitation of number of patients, a description of the operative technique, incidence of conversion to open if applicable, number of patients included in follow-up data per year, percentage of patients lost to follow-up, weight loss usually expressed as percentage of excess weight, initial and subsequent BMI, complications, mortality, resolution of medical comorbidities, and any quality of life data. Few publications have met these criteria. There are also only a few studies in which a prospective randomized comparison either between bariatric surgery and medical management or between different bariatric surgical operations or approaches (laparoscopic vs. open) have been performed. Improvement in study design and more complete data in future publications are indicated.

A multidisciplinary team approach to follow-up is as essential, if not more so, postoperatively than preoperatively. Regular counseling sessions with the nutritionist are always helpful. Psychological support should be available as needed to assist the patient in adjustment to major life changes. All programs should offer a frequent support group forum for patients to discuss issues on a less formal basis and receive encouragement from other patients as well as staff.

Experience of performing bariatric surgery for several decades between the co-authors has led us to conclude that whatever the operation performed, its long-term success is only achieved by patients if they embrace the eating and lifestyle changes the operation allows them to adopt. Continuation of exercise as part of the daily lifestyle is associated with a high incidence of preservation of weight loss. Diligence to avoid snacking and returning to other poor eating habits is also important. The majority of patients do embrace the metamorphosis their bariatric operation produces such that they maintain their new eating, lifestyle, and exercise habits to the benefit of their bariatric operation produces such that they maintain their future improved health, self-image, and well-being.

Laparoscopic Adjustable Gastric Banding

Background. LAGB involves placement of an inflatable silicone band around the proximal stomach. The band is attached to a reservoir system that allows adjustment of the tightness of the band. This reservoir system is accessed through a subcutaneously placed port, similar in concept to ports used for chemotherapy via central venous catheters. Figure 27-2 shows the LAGB apparatus in place.

Two major types of bands have been used for this procedure. The original Lap-Band, most recently marketed by Apollo Endosurgery, has been used most frequently. The Swedish Band, now remarketed as the Realize Band by Ethicon, is slightly wider than the Lap-Band. The port systems have differences as to profile and methods of attachment to the fascia.

Technique. Port placement for LAGB has varied among surgeons. Figure 27-2 shows a common configuration used. Usually some combination of two ports for the surgeon’s hands, one or two for the assistant, a port for the telescope, and a liver retractor site are needed.

With the patient placed in reverse Trendelenburg position, the procedure begins with division of the peritoneum at the angle of His and then division of the gastrohepatic ligament in its avascular area (the pars flaccida) to expose the base of the right crus of the diaphragm. If a hiatal hernia is present, it must be repaired at this point, using a standard posterior esophageal dissection to expose the crura and perform suture repair. A grasper (Lap-Band) or specially devised instrument (Realize Band) is inserted along the base of the anterior surface of the diaphragmatic crura, from right to left, emerging at the angle of

Figure 27-2. Laparoscopic adjustable band overall scheme. (From Schauer PR, et al, eds. Minimally Invasive Bariatric Surgery, 1st ed. New York: Springer; 2007. Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All rights reserved.)
His in the area of the divided peritoneum (Fig. 27-3). The device is then used to pull the band underneath the posterior surface of the gastroesophageal junction. This technique, by passing the band through some fibrous tissue in this plane, serves to anchor the band more securely posteriorly. During the initial years of band placement, a retrogastric location of the posterior half of the band in the free space of the lesser sac caused an unacceptably high incidence of slippage and prolapse of the band. The adoption of the *pars flaccida* technique decreased the incidence of such slippage.\(^9\)

Once the band is passed around the proximal stomach, it is locked into its ring configuration through its own self-locking mechanism. This involves the tubing end being passed through the orifice of the buckle for the Lap-Band and the suture on the end of the flanged end of the band site being passed through for the Realize Band. Once the band is securely locked in place, the buckle portion of the band is located on the lesser curvature of the stomach (Fig. 27-4A,B). Now the anterior surface of the fundus and proximal stomach is imbricated over the band using several sutures (Fig. 27-5).

---

**Figure 27-4.** A. Lap-Band in place around stomach. *(From Schauer PR, et al, eds. Minimally Invasive Bariatric Surgery, 1st ed. New York: Springer; 2007. Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2005-2009. All rights reserved.)* B. Realize (Swedish) Band around stomach.
The tubing of the band system is brought out through the desired site for placement of the port portion of the system. Usually this is a trocar site near the upper abdomen or xiphoid region to place the port most superficially such that it can be palpated postoperatively. The port is secured to the anterior abdominal wall fascia. Access to the port for subsequent addition of fluid to the band system is percutaneously achieved using a Huber or noncutting type needle. The band is initially placed empty of fluid in most circumstances.

**Patient Selection and Preparation.** Most LAGB procedures are done on an outpatient basis. Technically the operation is not as difficult as the other operations described later. Because the gastrointestinal tract is not violated, the relative risk of the procedure is lower than most other bariatric operations, making this procedure more amenable to offer to older, more medically ill, or higher risk patient populations. However, efficacy of the operation in the superobese (BMI >50 kg/m²) is less impressive, with average BMI remaining over 40 kg/m² after 5 to 8 years of follow-up. It has been our impression that optimal results occur with this operation in a patient population who is motivated, needs to lose less than 50 kg to achieve a BMI less than 30 kg/m², is willing and able to exercise regularly, is amenable to changing eating patterns as recommended, and is within a geographically close enough area for ease of follow-up. Patients who are impatient to lose weight, immobile, unable or unwilling to exercise, or confirmed “grazers” or “nibblers” on high-calorie sweets who expect to be able to continue their dietary habits without great alteration are not good candidates for this operation. Similarly, patients who have had previous upper gastrointestinal surgery, such as a Nissen fundoplication, are relatively poor candidates for LAGB due to the potential tissue compromise in taking down the wrap to place the band.

Important points of preoperative preparation specific to the procedure include being nil per os (NPO), receiving preoperative appropriate venous thromboembolism prophylaxis, appropriate broad-spectrum intravenous antibiotics, and having appropriate intravenous access and monitoring. An orogastric tube is inserted into the stomach. These preoperative measures are recommended in all the procedures described later as well.

**Postoperative Care and Follow-Up.** The majority of LAGB procedures are performed on an outpatient basis. Insurance requirement and pre-existing medical issues are usually the only reason for overnight hospitalization. Diet instructions, wound care, pain medications, and instructions on time schedule of resuming other preoperative medications should all be explained to the patient as well as to a family member (who has not just undergone general anesthesia) prior to discharge. Arrangements for a postoperative follow-up visit, phone numbers to call for emergencies, and indications to call should all be explained as well.

The first postoperative evaluation after LAGB generally occurs 2 to 3 weeks after surgery. By this time, patients have begun to tire of the blenderized diet recommended, are often eager to return to work if they have not done so, and are amenable to discussions of an exercise plan and diet progression plan. Wounds are assessed, as are medical problems, oral intake, and adherence to diet. Since LAGB does not preclude absorption of any specific nutrients, we only recommend a multivitamin for patients whose preoperative lab values are normal. Use of ursodiol (300 mg twice a day) for gallstone prophylaxis after LAGB is variable from surgeon to surgeon. Weight loss after LAGB often does not occur as rapidly as after gastric bypass, and data regarding gallstone formation after LAGB are lacking. However, rapid weight loss after LAGB will occur in some patients justifying prophylaxis with ursodiol.

Band adjustments and postoperative support group sessions are extremely important for good outcomes after LAGB. Band adjustments are paramount as part of the operation. The actual performance of the LAGB procedure is really only a small part of the care of the patient. Frequent postoperative visits, band adjustments as necessary, and participation in an appropriate exercise program are all important for postoperative success for these patients. Recommendations for timing of band adjustments vary from practice to practice. In general, there is agreement that losing less than 2 lb per week is an indication to increase the restriction of the band by adding fluid. Patients who can easily eat most solid foods and have little satiety and a fairly pronounced appetite need additional restriction from the band.

Band fills usually are accomplished in the outpatient clinic setting. Occasionally fluoroscopic radiology is needed to assist in accessing the port, based on the depth of the port from the skin and its ease of palpation. Experience by the person doing the band fill is an important factor in increasing the percentage
of patients able to be accessed in clinic without radiology assistance. A careful record should be maintained of the amount of fluid in each patient’s band. Some surgeons will withdraw all the fluid at each fill, reinserting the desired amount. Many will just add additional fluid as indicated. The amount of fluid added is based on hunger, weight loss, and ability to eat meat or bread. Figure 27-6 shows an in-office algorithm adjustment scheme used by Ren and colleagues at New York University. Ideally, adjustments are performed over approximately a 2-year period after surgery. However, changing life and clinical circumstances can require adjustments at any time thereafter.

An optimal situation for LAGB success is a program whose patients all live within an easy drive of the center, will and do participate in frequently available support groups and use exercise facilities supplied by the program, have access to band adjustment visits as needed, and are carefully selected for appropriateness and motivation for the procedure preoperatively.

Outcomes. Medium- to long-term (8-year follow-up) outcomes have been reported for LAGB from Weiner et al. At 5 and 7 years after LAGB, an average of published studies in the literature showed that patients lost 60% and 58% of excess weight, respectively. Resolution of comorbidities after LAGB has been reported as overall very good, with hypertension resolving in 55% at 1 year, observed sleep apnea decreasing from 33% to 2%, GERD improving in over 50% of cases, and asthma, depression, and quality of life improving for patients after LAGB. Dixon and colleagues published a landmark article describing the vastly superior results of managing patients with diabetes using LAGB versus optimal medical management. Resolution of diabetes was 13% in the medical group versus 73% in the surgical group after a 2-year follow-up.

Large institutional series of LAGB results have been published from centers in Europe and Australia, with good results for the Lap-Band. Similarly excellent results have been published for the Swedish adjustable band. Buchwald and colleagues performed a meta-analysis of all bariatric surgical papers published from 1990 to 2003. Overall mortality for LAGB was given as 0.1%. Table 27-6 shows the data from this paper and another meta-analysis for weight loss.

---

morbid obesity, and mortality for LAGB compared with RYGB and the malabsorptive procedures. Table 27-7 also shows data also from Buchwald and colleagues regarding the percentage of resolution of four major comorbidities associated with obesity after the most common types of bariatric operations, including LAGB.

Specific complications that may occur after LAGB include prolapse, slippage, erosion, and port and tubing complications. In addition, just plain failure to lose weight is more commonly seen with this procedure than with other common bariatric procedures.

Prolapse is perhaps the most common emergent complication that requires reoperation after LAGB. The incidence of reoperation is generally around 3%. Postoperative vomiting predisposes to this problem. The lower stomach is pushed upward and trapped within the lumen of the band. Typical patient symptoms include immediate dysphagia, vomiting, and inability to take oral food or liquid. Either anterior or posterior prolapse may occur. The initial evaluation for prolapse involves obtaining a plain film radiograph. If the band is in a horizontal position, prolapse must be strongly suspected. This orientation differs from the normal angulation of the band in the 1 to 2 o’clock and 7 to 8 o’clock positions of the two ends of the band on plain radiograph. Initial treatment for a prolapse is to remove all the fluid from the system. This often allows reduction of the prolapse and resolution of symptoms. If symptoms resolve, the necessity of performing an upper gastrointestinal series is lessened. If they do not, an upper gastrointestinal series is indicated, and if prolapse persists, then reoperation laparoscopically to reduce the prolapse and resuture the band in place is indicated.

Slippage has been greatly reduced by the pars flaccida technique, and operative need for repair now occurs in about 3% of cases in most series of short-term follow-up. Longer-term follow-up rates may show higher rates of prolapse. In our experience, a symptom-related need for band deflation, with suspected prolapse, occurs in 10% of patients.

Band erosion is uncommon, reported in 1% to 2% of most series. The patient usually becomes ill but not floridly ill, developing either a port site infection or systemic fever and a low-grade abdominal inflammatory sepsis. Endoscopy can be diagnostic. The presence of otherwise unexplained free air on computed tomography (CT) scan should alert the surgeon to this diagnosis as well. Laparoscopic removal of the band is indicated, with repair of any gastric perforation. Often the perforation is already sealed by an inflammatory process, but if not, appropriate management of a gastric perforation must be followed.

Port and tubing problems occur in approximately 5% of patients undergoing LAGB. These require revision of the port/tubing system due to perforation, leaking, or kinking of the tubing or turning of the port such as access to the surface of the port for adding fluid is precluded. Usually a procedure under local anesthesia is all that is required to repair or realign the tubing or port.

The incidence of band removal for patient dissatisfaction or lack of weight loss is difficult to assess, since this number is increasing annually at a not small rate. The figure also is likely related to patient follow-up and may be artificially low if the patient seeks a second surgeon to remove a band. The true incidence probably varies widely. Angrisani et al reported a 40.9% incidence of band removal after 10-year follow-up.

One of the positive outcomes of LAGB is the safety of the procedure. While complications are not rare, most of them involve non–life-threatening events. Nutritional complications are uncommon and easily treated. Based on worldwide data, the results appear to be optimal in those practices and centers where continued optimal follow-up and encouragement of appropriate behavioral lifestyle changes occur.

The Lap-Band also has its limitations, which may be the cause of its reduced popularity. It is often ineffective in producing adequate weight loss. Restriction of high-caloric liquids, easily digested snacks, and other foods that tend to negate dietary efforts is not adequately achieved with the Lap-Band. Patients must have enough willpower to avoid such foods. If weight loss remains poor, patient frustration and dissatisfaction increase as time passes postoperatively. In centers where suboptimal conditions exist for support and follow-up, the rate of band failure in terms of poor overall weight loss is significant. Reports in the literature tend to only include patients who still have their bands in place and exclude patients who have had bands removed for failure to lose weight. While the latter group of patients probably varies widely from center to center, the trend in many centers to now perform more LRYGB or SG and less LAGB than 5 years ago suggests that LAGB outcomes may rest as much on the postoperative support setting as the operation itself. Centers should reassess their ability to provide optimal follow-up and should do so if possible for optimal long-term results after LAGB.

### Laparoscopic Roux-en-Y Gastric Bypass

#### Background.

LRYGB was first described in 1994, but by 1998, only a few centers had accumulated any significant experience with the procedure. The University of Pittsburgh was one of those centers, with Schauer and colleagues performing the procedure, and instituted a large number of training courses from 1998 to 2001, which trained many of the bariatric surgeons who adopted the laparoscopic approach. By 2003, over 130,000 gastric

bypasses were done in the United States, with more than half of them being done laparoscopically. Currently over 90% of gastric bypass operations nationally are performed laparoscopically.

Figure 27-7 depicts the configuration of the LRYGB. The major feature of the operation is a proximal gastric pouch of small size (often <20 mL) that is totally separated from the distal stomach. A Roux limb of proximal jejunum is brought up and anastomosed to the pouch. The pathway of that limb can be anterior to the colon and stomach, posterior to both, or posterior to the colon and anterior to the stomach. The length of the biliopancreatic limb from the ligament of Treitz to the distal enteroenterostomy is 20 to 50 cm, and the length of the Roux limb is 75 to 150 cm. Longer Roux limb lengths are performed but considered to have more malabsorption than the standard gastric bypass.

Experience has resolved several controversies about gastric bypass, but others are still debated. It is clear that creating the proximal gastric pouch by totally dividing it from the distal stomach is superior to simply stapling the stomach, since the latter is associated with a high incidence of staple breakdown. The size of the proximal gastric pouch must be small to create adequate restriction and should be based on the lesser curvature of the stomach to prevent dilation over time. Length of the Roux limb is associated with higher short-term weight loss for longer length limbs, but this difference becomes less on long-term follow-up. Some surgeons doing LRYGB will create a longer (150 cm) Roux limb for patients with a BMI over 60 or even 50 kg/m². Antecolic position of the Roux limb is associated with a lower incidence of internal hernias leading to obstruction in most series with short-term follow-up. However, reports with longer follow-up suggest later internal hernia incidence may increase with an antecolic approach. Despite the plethora of enthusiasm for reoperative endoscopic narrowing of the gastrojejunostomy opening, good long-term data do not yet exist to confirm that size of the gastrojejunostomy can be related to weight loss. The gastrojejunal anastomosis can be constructed in a variety of ways. Smaller diameter circular staplers are associated with a higher incidence of postoperative stenosis, and linear stapling is associated with a lower incidence of stenosis compared to circular stapling.

**Technique.** The operation generally is performed using five ports plus a liver retractor. Both the surgeon, who stands on the patient’s right, and the first assistant, who stands on the patient’s left, have two ports for instruments. The telescope requires a port, usually in the supraumbilical region. The assistant’s ports are in the left subcostal and flank areas, while the surgeon may have both ports in the right upper quadrant (Cleveland approach) or one on each side of the camera (Virginia approach, Fig. 27-8). Division of the proximal jejunum at 40 to 50 cm distal to the ligament of Treitz is performed with the linear stapler, using the

white stapler cartridge. Further division of the mesentery at that location is performed either with the stapler or harmonic scalpel, such that adequate mobilization of the Roux limb is achieved. A Penrose drain or suture is sutured to the proximal Roux limb (Fig. 27-9) for identification and facilitation of advancement to the gastric pouch.

The length of the Roux limb (usually 100–150 cm) to be created is now measured. A jejunojunostomy is then created to the proximal end of the biliopancreatic limb at the above-determined location along the Roux limb. A side-to-side stapled anastomosis is performed (Fig. 27-10). Either single- or double-fired staple technique (the latter using a stapler fired in each direction) is used. The stapler defect is optimally closed with sutures but can be closed with a stapler if great care is taken not to narrow the lumen of the alimentary tract at this location. Once the stapler defect is closed, the mesenteric defect is then also closed with running permanent suture.

Passage of the Roux limb toward the stomach is now performed. If an antecolic route is to be used, the end of the Roux limb is brought up so as to confirm its ability to reach the stomach. If a retrocolic route is to be used, a defect is made in the transverse colon mesentery just to the left and slightly above the ligament of Treitz. The Penrose drain and the proximal end of the Roux limb are placed into the retrogastric space (Fig. 27-11).

The left lobe of the liver is now retracted using any one of several retractor types. The patient is moved to a reverse Trendelenburg position. The harmonic scalpel divides the peritoneum in the area of the angle of His. Then it is used to open an area along the lesser curvature of the stomach approximately 3 cm down from the gastroesophageal junction. Another approach for creating access to the lesser curvature of the stomach is to use a white or gray load (vascular load) of the stapler and divide the lesser curvature vessels up to the surface of the stomach. Then a blue load of the stapler is fired one time transversely from the lesser curvature side partially across the stomach, followed by multiple subsequent firings of the stapler upward in the direction of the angle of His, to completely separate the proximal gastric pouch from the remainder of the stomach (Fig. 27-12). Use of an Ewald tube passed by the anesthesiologist and maneuvered to lie against the lesser curvature of the proximal stomach can help calibrate the pouch size.

Once the pouch is created, the Roux limb is brought up to the proximal gastric pouch. For the linear stapled anastomosis, the proximal end of the Roux limb is aligned with the distal gastric pouch end, and the sides of the organs are sutured together to maintain their side-by-side position. A blue load of the stapler is introduced through a gastrostomy and an enterotomy for the two legs of the stapler, and the anastomosis is created (Fig. 27-13).
The stapler defect is closed with sutures and often reinforced with a second layer of sutures. At this point, the gastrojejunostomy is tested for security by using either methylene blue injected under pressure through the Ewald tube or a flexible upper endoscopy intraoperatively to test for air leakage from the anastomosis. The latter technique has been shown to decrease the incidence and seriousness of anastomotic leaks postoperatively.

The final step of the operation involves suture closure of all mesenteric defects using permanent suture.

Circular anastomosis for the gastrojejunostomy is accomplished through placement of the anvil of the stapler through the anterior wall of the proximal gastric pouch. This is accomplished by pulling the anvil transorally via an endoscopically placed guidewire (Fig. 27-14), making a gastrotomy in the pouch that is later closed, or making a gastrotomy in the lower stomach before completing gastric division to create the pouch, allowing the anvil to be placed into the lumen of the stomach and then be brought through the anterior stomach in an area that is subsequently included in the proximal gastric pouch (Fig. 27-15).

Hand-sewn gastrojejunostomy is usually created using two layers of absorbable suture to anastomose an approximately 1-cm gastrotomy and enterotomy.

**Patient Selection and Preparation.** LRYGB is an appropriate operation for consideration for most patients eligible for bariatric surgery. Relative contraindications to LRYGB include previous gastric surgery, previous antireflux surgery, severe iron deficiency anemia, distal gastric or duodenal lesions that require ongoing future surveillance, and Barrett’s esophagus with severe dysplasia. Contraindications to a laparoscopic approach to RYGB should cause the surgeon to choose an open RYGB or other open procedure instead.

Preoperative flexible upper endoscopy is indicated in all patients contemplating undergoing RYGB to rule out lesions of the stomach or duodenum noted earlier. Preoperative low-calorie diet for patients with hepatomegaly can decrease liver size and thus improve the chances of completing the operation laparoscopically. We use a mechanical bowel prep to decrease bowel weight and the chance of an inadvertent tear with handling using the laparoscopic graspers.

**Postoperative Care and Follow-Up.** LRYGB patients are usually hospitalized for 2 to 3 days. Major concerns on the night of surgery include adequate analgesia, adequate fluid resuscitation to provide adequate urine output, and early ambulation. We still routinely employ a postoperative oral contrast study

on the first postoperative day. Numerous studies have advocated abandoning this practice due to its lack of accuracy and cost-effectiveness.\(^89,90\) The study’s value to us has been to alert us to edema or stenosis of the enterostomy or any other obstructive pattern of the proximal bowel. Obstruction of the enterostomy or beyond can result in distal gastric dilatation over just a period of several hours, which, if untreated, can cause distal gastric staple line rupture with fatal consequences.

Aside from early ambulation, postoperative prophylaxis against venous thromboembolism includes compression shoes and low-molecular-weight subcutaneous heparin. Discharge on a blenderized diet is standard for our practice. Diet advancement occurs after the first clinic visit, usually approximately 3 weeks after surgery. At that time, an exercise plan is initiated if not already started.

Patients on insulin for type 2 diabetes and on antihypertensive medications should be monitored to determine whether reduction of their medication is indicated. Subsequent follow-up visits are usually scheduled for 3 months, 6 months, and 1 year after surgery, and then annually thereafter. The focus of later postoperative visits is documentation of outcomes and testing for postoperative nutritional deficiencies.

**Outcomes.** Patients undergoing LRYGB usually lose between 60% and 70% of excess body weight during the first year after surgery. This has held true since the earliest large series of this operation was reported.\(^91\) Resolution of comorbidities varies, but is over 90% for GERD and venous stasis ulcers and over 80% for patients with type 2 diabetes of less than 5 years in duration. Hyperlipidemias are almost always improved and resolve totally in about 70% of cases. Hypertension resolves in 50% to 65% of cases (see Table 27-7). Even superobese patients who do not achieve an ultimate BMI of less than 35 kg/m\(^2\) can experience significant improvements in comorbidities after LRYGB or open RYGB.\(^92\)

Mortality after LRYGB is now consistently less than 0.5% in most large reported series. Recent data from centers applying to be centers of bariatric surgery excellence showed a mortality rate of approximately 0.3% overall. The Bariatric Surgery Center Network (BSCN) of the ACS database showed a mortality of 0.14% at 30 days.\(^93\)

Overall morbidity after LRYGB has been acceptably low. In the BOLD database of the ASMBS, it was 14.87% for 30,864 gastric bypass procedures.\(^94\) In the BSCN database, the 30-day

morbidity rate was 5.91% for 14,491 LRYGB procedures. Reduced morbidity rate was 5.91% for 14,491 LRYGB procedures.93 LRYGB avoids most wound and incisional hernia problems. Complications that do occur include a 0.3% incidence of anastomotic leak,94 a 3% to 5% incidence of wound infections or problems,95 a 3% to 15% incidence of marginal ulcers,96 an approximately 7% incidence of bowel obstruction,97 a 4% incidence of postoperative transfusion,98 and a 1% to 19% incidence of anastomotic stenosis,99 based on the type of anastomosis created.

Postoperative nutritional complications after LRYGB include a 66% incidence of iron deficiency, a 5% incidence of iron deficiency anemia, a 50% incidence of vitamin B12 deficiency,100 and an at least 15% incidence of vitamin D deficiency,101 which usually is present preoperatively.

Several complications that are specific to LRYGB must be emphasized. One of the most important is small bowel obstruction. This complication must be treated differently than in the average general surgery patient, whose complication is usually from adhesions and often will resolve with conservative, nonoperative therapy. Patients who have had LRYGB who present with obstructive symptoms generally require surgical therapy on an emergent basis (Table 27-8). This is because the etiology of the bowel obstruction after LRYGB is often an internal hernia from inadequate or nonclosure of the mesenteric defects by the surgeon at the time of operation. Thus, treatment for these patients differs from most patients with small bowel obstruction. One of the most important points of this chapter is to emphasize to general surgeons to be aware of the need to emergently operate on patients after LRYGB who present with small bowel obstruction. Currently, centers that perform small bowel transplantation are seeing patient referral for that procedure after small bowel obstruction after LRYGB, where patients developed infarction of most of the bowel from an internal hernia and have short gut syndrome.102 Other patients, for whom surgery is delayed and the bowel infarcts, do not survive. When the surgeon does encounter bowel obstruction after LRYGB, he or she can expect to see proximally dilated bowel. Cutoff of passage of contrast on CT scan at the enterointerostomy is particularly suggestive of this diagnosis (Fig. 27-16). The surgical treatment of this particular problem can, if addressed early in the course of the obstruction, be treated laparoscopically. The surgeon must place a trocar for the telescope low enough in the abdomen to adequately survey most of the small intestine. The cecum and terminal ileum are identified, and the bowel is followed retrograde from the terminal ileum to determine the anatomy. Often much of the small bowel is herniated through a mesenteric defect, and only this technique allows the surgeon to reliably identify the bowel and decompress it appropriately. If the bowel is viable, suturing the mesenteric defect is all that is needed for treatment. It should be emphasized that either an antecolic or retrocolic placement of the Roux limb can result in this complication, as internal hernias can arise from either approach.

Marginal ulcers are another complication relatively specific to RYGB, either LRYGB or open RYGB. The patient presents with pain in the epigastric region that is not altered by eating. Diagnosis is by endoscopy. Treatment is medical with proton pump inhibitors, which are effective in 90% of cases. Only those with a gastrogastric fistula to the distal stomach, severe stenosis of the lumen of the gastrojejunostomy, or acute perforation require surgical therapy.

Stenosis of the gastrojejunostomy has been remarkably reduced by the use of a linear stapling technique in our experience.103 Stenosis symptoms usually appear from 6 to 12 weeks postoperatively, but less commonly can occur later. Diagnosis is by upper endoscopy. Treatment is balloon dilatation. Resolution normally occurs with one or two treatments. Less than 10% of patients require reoperation, and those are almost always associated with concurrent marginal ulcers.104

Figure 27-16. Obstruction of contrast at enterointerostomy with small bowel obstruction from internal hernia after laparoscopic Roux-en-Y gastric bypass.
In the immediate postoperative period, anastomotic leak is the single most feared complication after RYGB, either open or laparoscopic. Careful vigilance and a high index of suspicion for this problem are the only appropriate approach, since its presentation may be insidious and the patient’s demise, if untreated, sudden and complete. Tachycardia, tachypnea, fever, and oliguria are the most common symptoms that arouse suspicion for this problem. The treatment is surgical except in rare circumstances where a drain is already in place, no hemodynamic or clinical deterioration is present, and the leak is contained. Usually surgical treatment involves repair as feasible, drainage, and creation of a reliable feeding access through a distal Stamm gastrostomy.

In the first few hours or days after surgery, hematemesis indicates bleeding from the gastrojejunostomy unless proven otherwise. The dangers to the patient include aspiration, life-threatening hemorrhage, or more commonly intraluminal hematoma of the Roux limb and enterostomy, which then causes an obstruction of the biliopancreatic limb leading to distal gastric staple line rupture. In fact, any obstructive symptoms in the first few weeks after surgery or any signs of obstruction of the biliopancreatic limb on postoperative swallow studies due to stenosis of the enterostomy require immediate surgical intervention to prevent rupture of the distal gastric staple line. Some reports show that percutaneous decompression of the distal stomach can ameliorate the danger. Alternatively, operative therapy to decompress the stomach and treat the obstructive problem is also a reasonable option.

Overall, LRYGB has the significant advantages over open RYGB of avoiding incisional hernias and severe wound infections. Table 27-9 shows the data on these problems, comparing outcomes for laparoscopic versus open procedures at the University of Virginia. Compared with other bariatric surgical procedures, the LRYGB offers a reliable and powerful operation to allow the severely obese patient to lose weight. Although more reliable and greater, this weight loss does come at a slightly higher complication rate compared with LAGB and SG. However, these complication rates, as well as mortality, have been steadily decreasing for LRYGB in the past decade.

**Open Roux-en-Y Gastric Bypass**

**Background.** As described earlier in the chapter, Mason and Itoh first described gastric bypass, and Griffin and colleagues first described its Roux limb modification. It has been the most time-tested and proven of all bariatric operations. The procedure is now done virtually the same as LRYGB, with the only difference being the access route to perform it. Experienced bariatric surgeons who do not perform laparoscopic surgery still perform this operation with excellent overall outcomes, but their numbers are diminishing. RYGB was the most popular operation performed in the United States in the 1990s, but is now far exceeded by LRYGB and LAGB in terms of volume due to the preference of patients to undergo a laparoscopic rather than open procedure. However, for the patient for whom a laparoscopic approach fails, RYGB must be an operation that the bariatric surgeon can perform with skill.

**Technique.** RYGB is performed essentially the same as LRYGB. Some surgeons who use an open approach prefer to perform creation of the gastric pouch as the first part of the procedure, but in essence, the net procedure is the same. Access for open RYGB is usually through an upper midline incision, although a left subcostal incision has been reported to furnish adequate access as well. Closure of the midline wound is performed using a running monofilament suture. Subcutaneous tissues are thoroughly irrigated, and skin is closed with a skin staple.

**Patient Selection and Preparation.** Patient selection is essentially the same as for LRYGB, since the operation is the same. Extraordinarily large patients or those with multiple previous abdominal operations, particularly previous gastric surgery, left colectomy, and splenectomy, often require an open incision to perform RYGB. Abdominal wall thickness and liver size are other factors that may require an open incision approach. Patients who have an existing large midline incisional hernia are also candidates for an open approach.

**Preparation for open RYGB is identical to LRYGB.**

**Postoperative Care and Follow-Up.** The postoperative care of the patient undergoing open RYGB is very similar to that of the patient undergoing LRYGB. Larger volumes of fluid resuscitation and often more narcotic analgesics are required the day of surgery and often the next as well. Greater attention must be paid to the incision site for potential infection, since an inadequately treated wound infection in these patients can extend easily to the fascial level and cause significant tissue loss before it is fully diagnosed. The perioperative care of open RYGB patients is usually more intense, often because such patients are very large, and concurrently have severe comorbidities, making them higher risk overall for complications of all types. It is interesting, though, that since the era of LRYGB,

patients who still undergo open RYGB (usually due to intraoperative conversion) in our practice often are discharged within 1 day of the laparoscopic patients. Our overall length of stay has decreased for RYGB patients based on postoperative pathways geared toward LRYGB.

Postoperative follow-up visits are similar to those of LRYGB patients, with the first visit being timed to appropriately remove skin staples. Other visits, follow-up schedule, and blood testing are identical to LRYGB.

Outcomes. The weight loss statistics and patterns for RYGB are comparable to those of LRYGB, as would be expected. Postoperative deaths are slightly higher for RYGB, but this is almost certainly due to the patient population, which is often among the most severely medically compromised preoperatively. Flum and Dellinger\textsuperscript{106} showed that for a patient population on Medicare insurance, and hence largely disabled, RYGB had an across-the-board mortality rate of 2.0%. This rate is considerably higher than the 0.3% to 0.4% incidence that was reported for programs applying at that time as bariatric COEs and is in large part due to the patient population. Interestingly, in the report by Flum and Dellinger, surgeons with the most experience had a mortality rate of less than 1.0% for this patient population, suggesting that surgeon experience and patient selection by experienced surgeons influence mortality for RYGB.

One of the most important population studies showing the benefit of bariatric surgery was done in patients undergoing RYGB. Christou and colleagues\textsuperscript{107} showed a lower incidence of mortality (0.68% vs. 6.17%) in the 5-year follow-up of over 1000 patients undergoing RYGB versus over 5000 severely obese individuals who did not have surgery. This was a reduction of 89% in the death rate.

The incidence of postoperative complications for RYGB is higher than that of LRYGB, due largely to increased morbidity from incisional hernias and other wound-related problems (see Table 27-9). Other than incisional hernias, the long-term results of patients undergoing RYGB are similar to those undergoing LRYGB, including nutritional issues, weight loss, and overall resolution of comorbidities.

Biliopancreatic Diversion and Duodenal Switch

Background. BPD was first described by, and remains championed by, Scopinaro in Italy.\textsuperscript{32} The operation, which is shown in Fig. 27-17, involves resection of the distal half to two-thirds of the stomach and creation of an alimentary tract of the most distal 200 cm of ileum, which is anastomosed to the stomach. The biliopancreatic limb is anastomosed to the alimentary tract either 75 or 100 cm proximal to the ileocecal valve, depending on the protein content of the patient’s diet. This operation met with limited international popularity, due to the technical difficulty to perform it combined with the significant percentage of nutritional complications that arise postoperatively. However, the procedure did develop a devoted following among a few bariatric surgeons.

One complication that plagued the BPD was the development of a high incidence of marginal ulcers postoperatively. Hess and Hess\textsuperscript{33} and Marceau and colleagues\textsuperscript{108} separately described the adaptation of the DS operation, originally proposed by DeMeester and colleagues\textsuperscript{109} for treatment of bile reflux gastritis, to replace the gastric portion of the BPD. This new procedure was originally called BPD with DS. For ease of description, we now simply use the term duodenal switch (DS) to describe this procedure. It is illustrated in Fig. 27-18.
Currently BPD and DS represent together less than 3% of bariatric operations performed in the United States, and this rate could be as low as 1% to 2%. The lack of a significant number of surgeons offering the operation, especially via a laparoscopic approach, probably has a great deal to do with that statistic. BPD and DS are, however, recognized as standard bariatric operations performed in the United States, and this rate is currently BPD and DS represent together less than 3% of bariatric procedures. One report of laparoscopic DS showed that for patients with an average BMI of 60 kg/m², the average hospital stay was 4 days, average operation room time was 3.5 hours, and mean excess weight loss at 9 months was 58%.

The technique for BPD will be described for the open approach, but the laparoscopic approach essentially reproduces what is done with the open approach, using different access. Laparoscopic BPD and DS are very technically challenging operations, perhaps another contributing factor to the relatively low numbers of surgeons offering these operations. The BPD operation begins with performance of a distal subtotal gastrectomy. A residual 200-mL gastric pouch is created for superobese patients, or a slightly larger pouch is created for patients with a BMI under 50 kg/m². The terminal ileum is identified and divided 250 cm proximal to the ileocecal valve. The distal end of that divided ileum is then anastomosed to the stomach, creating a 2- to 3-cm stoma. The proximal end of the ileum is then anastomosed side-to-side to the terminal ileum approximately 100 cm proximal to the ileocecal valve. Some surgeons perform the anastomosis only 50 cm proximal to the valve, but in these patients, the likelihood of good protein intake postoperatively should be high. Prophylactic cholecystectomy is performed due to the high incidence of gallstone formation with the malabsorption of bile salts.

The DS procedure differs from the BPD only in the proximal gut portion of the operation. Instead of a distal gastrectomy, resection of all the stomach except for a narrow lesser curvature tube of the stomach is performed. The diameter of this tube is calibrated with a dilator and, if limited to a 32- to 40-French diameter, produces the optimal amount of weight loss while still allowing adequate oral intake. The duodenum is now divided in its first portion, leaving an approximately 2-cm length of duodenum intact beyond the pylorus. This end of the duodenum is then anastomosed to the distal 250 cm of ileum. This anastomosis is often done in an end-to-end fashion with a circular stapler. It is the most difficult portion of the DS procedure, and leak rates are slightly higher than with other anastomoses. The distal bowel configuration and cholecystectomy are similar to BPD.

Patient Selection and Preparation. Patients who undergo either BPD or DS must be prepared for the consequences of a malabsorptive operation. Frequent and large-quantity bowel movement after any large amount of oral intake is common. Patients who have this procedure must be willing to accept frequent, voluminous bowel movements and will also usually modify their eating pattern to restrict intake if access to a bathroom will prove difficult. Patients who undergo either operation must agree to close follow-up preferably by the surgeon. Internists and family physicians may not appreciate the issues related to protein-calorie malabsorption if they occur and treat the patients instead for congestive heart failure. Disastrous results may then occur. Patients must also have the financial means to afford the large number of vitamin and mineral supplements that must be taken to avoid nutritional problems in this patient population.

Given the increased incidence of postoperative nutritional and other complications relative to any of the restrictive operations, BPD and DS usually are recommended only for patients who have superobesity or for whom it is reasonable to believe they will not succeed with the diet and exercise requirements that form the basis for long-term success with restrictive operations. Patients who have failed a restrictive operation and are considering reoperation are candidates for these procedures.

Contraindications to the procedure include geographic distance from the surgeon, lack of financial means to afford supplements, and preexisting calcium, iron, or other nutrient deficiencies.

**Postoperative Care and Follow-Up.** Patients undergoing BPD or DS must be followed closely and with absolute completeness for nutritional issues long term. Postoperatively, BPD and DS patients face the same potential complications as seen after RYGB. Anastomotic leaks, pulmonary compromise and complications, gastrointestinal bleeding, anastomotic stenosis or obstruction, and infections are all potential concerns during the index hospitalization. The long gastric staple line and the duodenal stump and gastrojejunostomy of the DS and the duodenal stump and gastrojejunostomy of the BPD are all areas of anatomic concern postoperatively. Distal anastomotic problems can occur with either procedure as well. Thorough preoperative and postoperative counseling by a nutritionist versed in the operation and potential nutritional deficiencies is essential. Vitamin and mineral supplements must be taken regularly on follow-up, including oral supplements for iron, calcium, and vitamin B₁₂ and a multivitamin. Fat-soluble vitamins must be supplemented in parenteral form. Careful monitoring of protein intake and serum albumin is necessary. More frequent follow-up than with RYGB is needed; checkups at 2-month intervals for the first year and semi-annual or more frequent visits thereafter are appropriate.

**Outcomes.** Weight loss results with BPD or DS are both excellent and comparable. They also are very durable. One 18-year follow-up study after BPD showed a mean excess weight loss of 70% persisting for that duration of time.

Although most of the results of BPD or DS are after open operations, one report of laparoscopic DS showed that for 40 patients with an average BMI of 60 kg/m² the mean hospital stay was 4 days, average operation room time was 3.5 hours, and mean excess weight loss at 9 months was 58%.

Buchwald and colleagues reported that after RYGB, where intestinal anastomoses and gastric division create potential problems. Scopinaro and colleagues reported obstruction in 1.2%, wound infections in a similar rate, and marginal ulcer in 2.8% of patients. However, others found the incidence of marginal ulcer to be higher after BPD, causing the adoption of the DS. Preservation of the pylorus drastically reduces the significant incidence of dumping (poorly quantitated in most series) after BPD. The duodenal stump and gastrojejunostomy of DS also has a very low rate of stomal ulcer, unlike the gastrojejunostomy of RYGB.

Nutritional complications are by far the most frequent and concerning after both of these operations, particularly on long-term follow up. Scopinaro and colleagues reported a protein malnutrition rate of 7%, iron deficiency anemia rate of less than 5%, and bone demineralization at 5 years of 53%. Other problems that may arise include alopecia from inadequate protein absorption, night blindness from a lack of vitamin A, and
gallstones if the gallbladder is not removed. However, of all these nutritional complications, protein-calorie malnutrition is the most severe and life-threatening. When it is diagnosed, the treatment is parenteral nutrition. Two episodes of required parenteral nutrition are usually considered adequate indication to lengthen the “common channel” of ileum—the ileum between the ileoileostomy of the biliopancreatic limb to the alimentary tract and the ileoceleal valve. The amount that the surgeon should lengthen it is poorly documented, but most surgeons will favor making it long enough to be certain to avoid recurrence of the problem, such as doubling the length of the common channel, even if it decreases weight loss somewhat.

It cannot be emphasized enough that patients who undergo either BPD or DS should be impressed with the fact that lifetime nutritional supplements and lifetime follow-up are essential to preserve good health after these operations.

Laparoscopic Sleeve Gastrectomy

Laparoscopic sleeve gastrectomy has taken the bariatric surgical scene by storm over the past 5 to 10 years. It is rapidly increasing in popularity, and by the time this book is published, it may be, in some countries and areas, the most popular bariatric and metabolic operation performed. Its rapid rise in popularity coupled with good initial results suggest that it will be a major component of patient care for the treatment of morbid obesity and its comorbid medical problems for years to come in the future.

Since sleeve gastrectomy is performed almost exclusively using a laparoscopic approach, the remainder of this text will use the simple term sleeve gastrectomy (SG) to describe the procedure, with the understanding that it is routinely performed using a laparoscopic approach. SG has its origins in the early days of laparoscopic bariatric surgery. The procedure represents the gastric portion of the DS procedure. Ren and colleagues reported an initial experience of performing DS using a laparoscopic approach that had relatively higher mortality than seen with gastric bypass or other treatment options being performed laparoscopically. This was in part due to the fact that patients selected to receive DS often were significantly larger and had more numerous and more severe comorbid medical problems. Gagner began to perform the gastric resection portion of the DS operation as a first-stage procedure. After patients had lost weight, the malabsorptive component of the procedure was then performed. However, many of the patients had such good results after the first stage of the procedure that they refused to proceed to the second portion. Thus, the concept of performing SG as a primary procedure was born.

Until 2009, SG was considered an “experimental” procedure by insurance carriers. That year, the ASMBS reviewed the data on the procedure and published a statement in January of 2010 recognizing the procedure had adequate data and results to support its use as a primary bariatric operation for carefully selected patients. Shortly thereafter, SG received a designated Common Procedural Terminology (CPT) code. Since that time, insurance carriers have recognized the procedure as being appropriate for treating severe obesity and its comorbid problems. The final carrier, Medicare and Medicaid in the United States, issued a statement in April 2012 that left the determination of coverage of this procedure to the regional insurance carriers administering Medicare. This happened only after a hearing to determine coverage in which a great deal of data was presented in favor of the procedure. The initial conclusion of that panel was that SG should be reimbursed if performed in the setting of a prospective randomized trial. However, subsequent public opinion and data caused CMS to revise its decision to allow regional carriers to determine coverage.

SG has the advantage of being a technically easier operation to perform than gastric bypass, while achieving better efficacy in treating comorbid medical problems and producing superior weight loss than LAGB. Once the results of the procedure began to be published, understood, and accepted, its popularity rose dramatically. In the United States, the incidence of performing SG has risen rapidly since 2008, as shown in Fig. 27-19. The incidence of SG is increasing at a rate that suggests that within the next 2 years it may pass LRYGB as the most popular bariatric operation performed in the United States.

Throughout the rest of the world, the popularity of SG has also risen dramatically in the past 5 to 8 years. In Asia, where there is a high incidence of gastric cancer in countries such as Japan, SG makes more sense anatomically as an appropriate treatment for severe obesity. In India, where the high incidence of diabetes in the obese population makes metabolic and bariatric surgery a desirable option, SG has gained popularity once its effectiveness in treating diabetes was shown. Figure 27-20 shows the trend in performance of several bariatric operations in Asia from 2003 to 2011, during which the totals of those procedures from surgeons surveyed increased over 500%. This rise in bariatric and metabolic surgery was comparable to the same increase in percentage of cases performed seen in the United States from 1998 to 2003. In Europe, the past few years have seen a clear trend away from performing LAGB and a higher incidence of performing both SG and LRYGB.

Indications. Patient selection for SG is comparable to that for other bariatric and metabolic operations with a few notable exceptions. SG was originally introduced as the first of a two-stage operative treatment for patients with super obesity (BMI >60 kg/m²). It remains an effective first- or second-stage treatment for such patients. Whether a second stage is indicated depends on the effectiveness of the SG. SG has been shown to be safe and effective in adolescent obese patients. It has also been shown to be an acceptable procedure for the elderly obese patient. SG effectively treats most of the comorbid medical problems associated with obesity. The one exception is GERD. Patients with GERD experience less resolution of their symptoms after SG than do patients with LAGB, even when the LABG patients lost less weight overall. Patients who have longstanding severe GERD may not be good candidates for SG. Barrett’s esophagus is considered a relative contraindication for performing SG, since the potential for future esophagectomy and the need for an available intact stomach for reconstruction outweigh the potential advantages of the procedure.

Technique. The patient is positioned supine, with foot support to allow reverse Trendelenburg positioning. The surgeon stands to the patient’s right along with the camera driver, while the assistant stands to the patient’s left. Port placement may vary from institution to institution, but our recommended port placement is shown in Fig. 27-21. The 15-mm port, helpful for removal of the stomach, is located in either the camera (just to the patient’s left of the umbilicus) or surgeon’s right hand (right upper quadrant near the midline) location. The other of these ports is a 12-mm port. The assistant has two 5-mm ports available in the left upper quadrant laterally, and the surgeon’s left hand port is a 5-mm port more lateral and superior in the right upper quadrant. A liver retractor is placed in the epigastric region. This can be a Nathanson or T-Boone retractor.

The operation begins by devascularizing the greater curvature of the stomach, beginning 3 to 5 cm proximal to the pylorus. The harmonic scalpel works nicely to perform this tissue division. The division of all vessels adjacent to the greater curvature is continued up to the left crus of the diaphragm. A complete mobilization of the fundus in this area and division of posterior fibrous attachments to the antrum and body of the stomach are then performed such that the stomach is attached solely by the lesser curvature blood supply and the pyloric and esophageal regions. Stapled division of the stomach now follows. The first firing of the stapler occurs from the point of devascularization of the greater curvature at an angle pointing toward a point about 2 cm lateral to the incisura. The antrum of the stomach is at its thickest here, and so it is important to be certain the stapler load used is sufficiently large enough to allow good approximation and closure of the divided stomach. We have favored use of the black load (2.5-mm staple height) in all males with a BMI over 45 kg/m², females with a BMI over 55 kg/m², or anyone whose stomach looks particularly thick. A green load (staple height of 2 mm when closed) is used for less thick stomachs or smaller individuals. We continue the use of this color load for the first two firings, which takes the gastric division to past the incisura. After the first staple firing, some surgeons will engage the anesthesiologist to pass a 32- to 36-French bougie and position it along the greater curvature of the stomach. This bougie then serves as a guide for further gastric division. Alternatively, some surgeons will insert the endoscope instead of the bougie as a guide for gastric division. It can also be used to test for air
leaks, bleeding, or obstruction as it is withdrawn after gastric division. Dividing the stomach adjacent to the bougie or endoscope will produce the desired diameter of the gastric sleeve. It is most important not to narrow the stomach lumen at the incisura. During the second and third firing of the stapler to divide the stomach, it is critical to confirm by visualization of both the anterior and posterior surfaces of the stomach that the incisura area is not narrowed. By the third firing of the stapler, usually the angle of the gastric division is now pointed directly toward the angle of His, parallel to the bougie (Fig. 27-22). At this point, changing staple loads to lower staple height is advisable. We usually switch to gold then blue staple loads as we progress proximally in dividing the stomach. It is essential that with each firing of the stapler, adequate time (10–20 seconds) is allowed for tissue compression to allow optimal staple closure and security of the divided tissue.

Once the stomach is completely divided up to the angle of His, the staple line is inspected for hemostasis and integrity. Some surgeons will reinforce the staple line with a buttress material, while others will invaginate the staple line with a running serosa to serosa suture. Some surgeons will exchange the bougie at this point for a 32-French Ewald tube and perform a methylene blue leak test. Alternatively, if an endoscope is used, it is withdrawn with insufflation, and the staple line is inspected for air leaks while submerged in saline. The specimen is removed through the 15-mm trocar site, usually with only slight enlargement of the site. Figure 27-23 shows the completed operation.

Controversy still exists as to the optimal size of the bougie used during the procedure. One summary of the literature shows that the stenosis rate is lower if a 40-French bougie is used, and the leak rate may also be lower without compromising weight loss. However, individual institutional experiences with smaller-sized bougies have shown the potential for exceptionally good weight loss and no increased incidence of stenosis. Another controversial area is that of staple line reinforcement with staple buttressing material. Some surgeons advocate routine staple line reinforcement, whereas others advocate none. Still others advocate oversewing of the staple line in areas of bleeding or in selected cases that show a predilection for bleeding intraoperatively. Other experts advocate routine oversewing of the entire staple line. At this time, there is no preponderance of data to support one approach as being superior to others.

Postoperative Care and Follow-Up. SG usually is performed with an overnight stay of 2 nights after surgery. Longer hospitalizations are indicated for patients with more severe medical problems. Absence of signs of bleeding and a documented intact staple line with good gastric emptying are required prior to discharge. Routine Gastrografin swallow on the first day after surgery is used by many surgeons, but its efficacy and cost-effectiveness have yet to be clearly documented. Follow-up is similar to that after LRYGB. Few nutritional complications occur unless the patient has difficulty taking in enough nutrients or protein or vitamins due to edema or tightness of the sleeve lumen. Most surgeons advocate routine vitamin B12. Iron supplementation may be required as well since iron in the diet is usually drastically restricted by elimination of many foods rich in iron. It is unclear whether the same need for vitamin D supplementation seen after LRYGB is also needed after SG, since there is a high incidence of low 25-hydroxyvitamin D levels preoperatively in patients undergoing SG. Routine multivitamins are usually prescribed to avert any potential other shortages from dietary vagaries.

The other aspect of weight loss that must be considered in the nutritional aspects of postoperative care and follow-up after SG is that patients are at risk of losing significant lean body
mass while they are also losing weight. Damms-Machado and colleagues\(^2\) showed that SG patients’ lean body mass decreased from 74.8 kg to 62.3 kg at 1 year after SG. This emphasizes the need for high protein content in the postoperative diet of SG patients to maintain lean body mass.

**Outcomes and Complications.** Reports in the literature of the success and excellent weight loss after SG have been accumulating since 2006.\(^{122,123}\) The first very large series from a single institution reported 750 patients undergoing SG as a primary weight loss procedure. Five-year follow-up of some patients was available, and a hospital stay averaging 1.7 days, a major complication rate under 5%, an operative time under 80 minutes, and no conversions or mortality were reported.\(^{124}\)

Brethauer and colleagues\(^129\) published an excellent review of the early data on SG through 2009. For the collected number of patients treated with SG (2750 patients), the excess weight loss rate was 55.4%. Studies with 5-year follow-up for SG are not yet common. One highly successful series was recently reported by Rawlins and colleagues\(^93\) for 49 patients followed for 6 years after SG with an average weight loss of 86% of excess weight and a decrease in average BMI from 65 to 35 kg/m\(^2\). One of the longest follow-up studies for SG by Eid and colleagues\(^129\) demonstrated an average excess weight loss of 48% and BMI decrease from 66 to 46 kg/m\(^2\) in 74 superobese patients with 6- to 8-year follow-up.

Prospective randomized trials comparing SG with other procedures have shown that SG is superior to LAGB for excess weight loss at 3 years (66% vs. 48%).\(^{127}\) One study reported that SG achieved a superior excess weight loss compared with LRYGB (69.7% vs. 60.5%) at 1 year after surgery. This study also found greater appetite suppression and a lower serum ghrelin level for SG.\(^{128}\)

SG has been included in the results of large databases showing outcomes after bariatric surgery. Data from the ACS BSCN showed that SG was positioned between LAGB and LRYGB for efficacy of weight loss and resolution of comorbid medical problems and for morbidity and mortality.\(^{93}\)

As noted earlier, controversy exists as to whether the use of buttress materials with the stapling of the stomach improves outcomes. The overall bleeding rate for the staple line after SG is generally cited as about 2% in collected series.\(^{125}\) There have been no studies that have shown a definitive decrease in this bleeding rate with the use of buttress materials; however, a panel of experts has voiced support for a decreased incidence of bleeding from the staple line if buttress material is used.\(^{120}\)

Measures to prevent staple line leakage are similarly controversial with respect to buttress materials and other measures. It is certain that appropriate stapling technique in dividing the stomach is important. Using an adequately high staple height for the tissue to be divided and allowing an adequate amount of time for tissue decompression within the stapler jaws before firing are essential to minimize the likelihood of a staple line leak. Failure to perform gastric division appropriately in this fashion will lead to an early staple line leak after surgery. Whether buttress materials do decrease the leak rate with SG is very controversial. One meta-analysis did show that there is evidence to suggest buttress materials may decrease this rate.\(^{129}\) Other prospective randomized studies have failed to show a benefit of buttress materials.\(^{130}\) To date, the literature has not clearly shown a benefit for using buttress materials in terms of leak prevention.

Perhaps the major factor that is different in SG than other gastric stapling procedures is that SG creates a high-pressure gastric tube. This increased intraluminal pressure places the staple line at risk for leakage. If there is a relative obstruction or stenosis of the sleeve, which most often may occur at the incisura due to narrowing there during formation of the sleeve, pressure above the level of the obstruction will be even more elevated and create an increased risk for staple line leak. Leaks of the proximal staple line are the most frequent type seen after SG and often are felt to be related to increased intraluminal pressure distally. They may also be related to stapling too close to the angle of His, with resultant instability of the tissue directly adjacent to the esophagus in this area. It is important not to staple too close to the angle of His during the final stapling division portion of the stomach so as to not further weaken the staple line in this area. Proximal staple line leaks may also present as late leaks. Late leaks are generally felt to be those that occur 6 weeks or longer after surgery. Late leaks are rare in other bariatric procedures, but are seen with SG. The increased pressure of the system may be a reason SG is associated with late leaks. Confirmation and treatment of stenosis symptoms early after SG may prevent such leaks.

Distal staple line leaks are different from proximal staple line leaks, and are usually associated with earlier presentation and related to mechanical failure of the staple line to securely approximate the thicker distal gastric tissue. These leaks are more amenable to successful repair with a reoperation, whereas proximal leaks may not improve with over-sewing at a reoperation unless the mechanics of the relative distal obstruction and high intraluminal pressure of the sleeve are also treated. Endoscopic intervention to dilate stenotic areas as well may be beneficial in the setting of a stenosis with or without a proximal leak. Care must be taken by the endoscopist to not excessively dilate the tract beyond the original size of the bougie used. Another factor that may influence stenosis at the incisura is that there may be a relative twisting of the stomach at this location, with the antrum being partially twisted away from the upper portion of the sleeve. Endoscopic treatment can help straighten and markedly alleviate the obstruction in such cases. Thus relatively early endoscopic intervention is appropriate in the patient with a stenosis at the incisura. One study has shown that endoscopic dilation is usually successful in treating stenosis after SG, with a mean of 1.6 dilatations being done an average of 48 days postoperatively.\(^{131}\)

The patient with the proximal gastric staple line leak due to mechanical factors may experience a persistence of the leak for months. Such cases are now only recently being published and discussed in the literature. It is unclear how long one should optimally treat such a leak conservatively with the likelihood it will close. Reports of such leaks persisting for multiple months postoperatively do exist. Our own experience has been that eventual closure of such a leak is possible even 4 months postoperatively. However, longer duration leaks are less likely to close. Some experts have now advocated conversion of the patient with a longstanding leak after SG to a RYGB to provide a low-pressure anastomosis above the site of the stenosis. Similarly, persistent stenosis of the sleeve despite conservative therapy and endoscopic dilation also is an indication for conversion to LRYGB.

**Physiology of Weight Loss.** SG is a fairly simple technical operation, amenable to performance by many surgeons. The results of the operation for weight loss have been excellent.
and dramatic. However, the mechanisms of the resolution of comorbidities, such as diabetes, are still not totally clear. While weight loss alone may provide the majority of the physiologic changes that improve comorbid problems such as diabetes and hypertension, it is also possible that other factors may be involved. Certainly SG, through gastric resection, eliminates much of the ghrelin-producing portion of the stomach. The resolution of type 2 diabetes after SG is remarkable, although not as good as that seen after RYGB. The reasons for this are as yet unclear, since lap RYGB has been shown to have independent factors influencing glucose metabolism separate from weight loss alone. The hormonal and peptide changes produced by SG in terms of appetite suppression, glucose metabolism, and other metabolic pathways have yet to be clarified. A recent hypothesis summarized by Ed Mason is that the rapid emptying of the stomach after SG creates a similar exaggerated release of GLP-1 as seen after LRYGB, and this results in the improved carbohydrate metabolism and improvement of type 2 diabetes seen after SG, as after LRYGB.

There is some concern among the bariatric surgical community that SG, because it is technically not that difficult, could become a procedure performed by surgeons without a full support system and follow-up mechanism for bariatric patients. The bariatric surgery community feels strongly that this procedure should remain a procedure done within the confines of the COE framework. This will ensure optimal patient outcomes.

**SPECIAL ISSUES RELATING TO THE BARIATRIC PATIENT**

### Bariatric Procedures in Adolescent and Elderly Patients

The incidence of obesity in the U.S. population has risen dramatically during the past two decades. This increase has included children and adolescents as well. The incidence of obesity (BMI >30 kg/m²) is estimated to exceed 25% in the adolescent population. Factors felt to contribute to this include decreased participation in physical sports and activities, increased time playing computer and screen games, and increased consumption of fast food and processed foods.

Obese adolescents have a high likelihood of being obese adults. In one study, 75% of adolescents above the 85th percentile were obese as adults. The social stigmatization of the severely obese adolescent is often brutal. Comorbid medical problems may already be present in severely obese adolescents, including hypertension and type 2 diabetes. The overwhelming likelihood of a severely obese adolescent facing a lifetime of severe obesity as an adult also implies that an average of 12 years of life for males and 9 years of life for females will be lost due to this medical problem.

The major controversy with regard to adolescents undergoing bariatric surgery includes the general aversion of subjective an adolescent to surgery as well as the concern of the secondary side effects of bariatric surgery on remaining growth and development. Clearly the younger the patient, the more relevant the latter concern becomes.

The literature to date on the results of outcomes from bariatric surgery on adolescents is generally quite favorable. However, it is still limited. Sugerman and colleagues reported on results for 33 adolescents, 30 of whom had RYGB (mostly open RYGB). There were two late deaths at 2 and 6 years of follow-up unrelated to surgery. There were 20 early and late complications, including six incisional hernias and five wound infections. Significant weight loss was maintained in the majority of patients for up to 14 years after surgery. Most comorbidities resolved at 1 year after surgery. Self-image was greatly enhanced and social stigmatization greatly decreased. Capella and Capella reported on 19 adolescent patients treated with a modified version of open RYGB in which a vertical band was added to the pouch. After an average 5.5-year follow-up, average BMI for the group was 28 kg/m². No deaths occurred, but two patients required revisional surgery. No mortality or morbidity was reported, and all comorbidities resolved.

Abu-Abied and colleagues treated 11 adolescents with LAGB. No late complications occurred, and after a 4-year follow-up, BMI averaged between 46.4 to 32.1 kg/m².

A meta-analysis involving 131 adolescents undergoing bariatric surgery demonstrated a 17.8 to 22.3 kg/m² decrease in BMI after RYGB. They also observed improvement of hypertension in more than half the patients and sleep apnea resolution in all 131 patients. There were four mortalities in this cohort, but only one of them was potentially associated with the procedure (. Clostridium difficile) colitis 9 months after operation). Morbidity in the adolescent literature ranges from 0% to 38% and tends to be minor in most cases. The most common complication in the meta-analysis was nutrient deficiencies. The weight of the evidence supports adolescent bariatric surgery as a safe and effective treatment of severe obesity in adolescents. The ASMBS pediatric guidelines suggest using BMI criteria similar to the adult population but with some modifications to comorbidity thresholds. They recommend considering surgery in patients with a BMI of 35 kg/m² or greater with major comorbidities (e.g., type 2 diabetes, severe nonalcoholic fatty liver disease, OSA) or a BMI of 40 kg/m² or greater with minor comorbidities (e.g., hypertension, dyslipidemia, insulin resistance).

The elderly patient population certainly suffers from severe obesity. However, data on the effect of nonsurgical therapies in treating this patient population are lacking. Similarly, it is likely that the patient who becomes obese late in life has a significantly different prognosis than the individual who has been severely obese and does manage to survive to an older age despite the resulting comorbidities.

There has been an increasing tendency to offer bariatric surgery to patients over the age of 60. Studies have documented that this patient population can have the same good outcomes and resolution of comorbidities as younger patients. Nehoda and colleagues reported equally excellent results for LAGB in patients over age 50 compared with those under age 50. Excess weight loss of 68%, reoperation rate of 10%, and 97% improvement in comorbidities were reported for this age group. A recent retrospective review of 42 carefully selected bariatric surgery patients over 70 years old looked at the outcomes up to 1 year after surgery. Of these patients, 22 patients (52.4%) underwent laparoscopic gastric banding, 12 patients (28.6%) underwent laparoscopic SG, and 8 patients (19%) underwent LRYGB. They safely achieved a mean weight loss of 47.7% with no mortality and modest improvement in obesity-associated comorbidities. SG for elderly patients is also gaining popularity. In 35 patients ≥60 years of age, Soto and colleagues demonstrated greater than 60% excess weight loss at 48 months with low morbidity (8.4%) and no mortality with SG.

Although these data show that in selected older patients excellent results can be obtained, surgeons must be cautious to
determine which patients have been severely obese for decades and therefore have essentially end-stage organ function in many cases as a result of the comorbid medical conditions that have been present for decades. Flum and Dellinger showed that the older patient population, especially those few patients older than age 70 undergoing bariatric surgery, did have an increased incidence of mortality and morbidity after RYGB.

The concept that bariatric surgery confers an improved quality of life, a longer life, and a life without as many associated medical problems leads to the logical conclusion that the benefits of an operation will be more fully realized in the younger patient. This philosophy, in view of the large number of unserved patients, does justify age limits for individual surgeon practices. While some surgeons do have such limits, patients near or just over the age limit are often reviewed on an individual basis to determine their appropriateness for surgery. However, some surgeons will base their decision on “physiologic” age rather than chronologic age because many elderly patients may be reasonably low risk for major complications. Accumulation of data may also change these limits in the future.

### The Female Patient: Pregnancy and Gynecologic Issues in the Bariatric Surgery Patient

Hormonal levels in female patients are related to body weight. Obesity alters the levels of estrogen and progesterone available for normal ovulation, resulting in abnormal ovulation patterns, amenorrhea, and difficulty conceiving. Should an obese woman become pregnant, the increased chances of gestational diabetes and hypertension make the pregnancy high risk. Macrosomia is increased. There is a two- to three-fold increase in the rate of cesarean sections, with more complications. Fetal mortality does not appear to be changed when maternal weight gain is limited. With obesity, there is an increased risk for breast and endometrial cancer in the postpartum mother.

Infertility compounds the difficulties of the obese woman who wishes to have an uncomplicated pregnancy and delivery. The same hormonal alterations that cause an increased incidence of cancer (i.e., increased circulating estrogen levels) also cause infertility. If a severely obese woman becomes pregnant, the pregnancy management is made more difficult by the body habitus and the need for more frequent ultrasounds as opposed to physical examination, which yields limited information.

Women who become pregnant soon after undergoing bariatric surgery can be at risk due to the ongoing weight loss produced by the operation. However, if the pregnancy is quickly recognized and appropriately managed, patients after bariatric surgery may actually have a better prognosis than if they had not had surgery. Wittgrove and colleagues showed that patients who had undergone RYGB had a decreased incidence of diabetes, macrosomia, and cesarean section than those who had not had surgery. However, iron replacement was cited as a critical need for these pregnant women. Despite these good results, there are issues for the female patient who undergoes RYGB and becomes pregnant during the rapid weight loss phase after surgery. Special attention is needed to assure adequate intake of vitamins and essential nutrients during what otherwise would be a period of rapid weight loss. Although no clear consensus exists regarding management of pregnancy after bariatric surgery, Beard and colleagues provide the following sound advice: (a) promotion of reliable contraception for 12 to 18 months after surgery; (b) close nutritional and weight monitoring during and after pregnancy; (c) supplementation to include daily prenatal vitamin, folate 400 μg, iron 50 to 100 mg, calcium 1000 mg, and protein 60 g; and (d) collaboration with high-risk obstetrical colleagues as needed.

Patients who become pregnant after LAGB would seem to have even less likelihood of significant risk to their pregnancy, since the band can be adjusted to allow more food intake during the pregnancy but similarly limit weight gain to a healthy amount. Dixon and colleagues wrote that morbidly obese women do have higher risks during pregnancy, but LAGB allows weight loss, which reduces such risk. The adjustability of the band provides a potential advantage for the pregnant woman.

Weight loss after bariatric surgery can correct the high incidence of gynecologic problems that may exist as a result of severe obesity. Deitel and colleagues found menstrual irregularities in over 40% of patients preoperatively, which became normal in over 95% of patients postoperatively. Infertility problems were present preoperatively in 29% of patients, and medical problems were frequent during previous pregnancies including hypertension in 26.7%, preeclampsia in 12.8%, diabetes in 7%, and deep vein thrombosis in 7%. These problems were virtually eliminated after weight loss. Stress urinary incontinence in the female patients in that study decreased from 61.2% to 11.6% after bariatric surgery.

Polycystic ovary syndrome (PCOS) is another common hormonal dysfunction associated with severe obesity. It is associated with obesity, infertility, hyperandrogenism, dyslipidemia, anovulation, insulin resistance, and abnormal menses. Bariatric surgery improves not only metabolic disease but also menstrual irregularity, hirsutism, and infertility associated with PCOS.

Stress urinary incontinence is a frequent problem of the severely obese woman, which must be specifically solicited on history. The increased intra-abdominal pressure from severe obesity contributes to the high incidence of this problem in the severely obese population. Obesity may also alter the neuromuscular function of the genitourinary tract, contributing to incontinence. Studies have confirmed the increased incidence of obesity in patients with both true stress incontinence and detrusor instability. Weight loss alone relieves symptoms in many patients with obesity. A recent study involving 72 patients who had bariatric surgery (90% RYGB) showed a nearly 50% reduction in prevalence and severity of urine incontinence after surgery based on objective urodynamic testing. A significant improvement in subjective quality of life and sexual function was also achieved.

### Metabolic Surgery

Advances in the role of metabolic surgery to treat type 2 diabetes mellitus (T2DM) and increases in the understanding of how surgery improves or resolves T2DM continue to represent the single most prominent change in the field of bariatric surgery since the last edition of this text. Nearly all international bariatric surgery societies have added “metabolic” to their name, including the American Society for Metabolic and Bariatric Surgery (ASMBS), which was formerly the American Society for Bariatric Surgery (ASBS). International meetings on the topic of bariatric surgery and its effects on diabetes have convened during the last 5 years to establish new guidelines regarding indications for metabolic surgery for T2DM as well as research priorities. The entire field of bariatric surgery is now much more focused on the metabolic effects and benefits of bariatric surgery.
Although many comorbidities are improved by bariatric surgery and its resultant weight loss, the metabolic diseases that are most particularly affected are T2DM and the hyperlipidemias and metabolic syndrome. Hypertension and cardiovascular disease are also improved indirectly through metabolic benefits as well as directly through weight loss effects.

**Type 2 Diabetes.** There has been a dramatic increase in the potential application of surgical therapy to treat T2DM. Much of this stems from the original observations of surgeons performing RYGB concerning the improvement or near resolution of T2DM well before patients who had undergone the operation had achieved maximum weight loss. Pories and colleagues championed these observations in a landmark paper that confirmed RYGB as an effective treatment for T2DM, resolving the condition in 85% of patients who had developed it within the 5 years prior to surgery. MacDonald and colleagues, also from the same institution, showed that treatment with RYGB of patients with T2DM resulted in longer life span. Schauer and colleagues showed that improvement in T2DM after LRYGB is comparable to that seen in Pories’ original work, with fasting insulin levels and glycosylated hemoglobin levels returned to normal levels in 83% of patients and markedly improved in 17% of patients. RYGB has been shown to decrease overall long-term mortality related to diabetes in several large population studies.

These results and studies, as well as the observation that T2DM resolved quickly after RYGB, led to the general belief that there is an important contribution of the enteric hormonal component of glucose metabolism influencing the disease. Rubino and Marescau reported the resolution of diabetes in the obese rat model with surgical diversion of the food stream from the duodenum and proximal jejunum. Reversal of the operation led to return of the disease state. The extension of the findings of Rubino and Marescau to humans has occurred; a duodenojejunal exclusion operation has been performed and shows initial safety and efficacy in a small group of patients. Although the majority of patients who have T2DM are obese, approximately 10% of patients with T2DM are not obese, and these data from Brazil may confirm that the resolution of the disease through enteric diversion is not based on associated weight loss.

Surgical therapy that does produce weight loss without diversion of the enteric stream also can be quite effective in resolving T2DM. Dixon and colleagues reported, in the first randomized controlled trial comparing surgical versus medical treatment of diabetes, that 73% of patients undergoing LAGB and followed for 2 years achieved resolution of T2DM versus 13% of medically treated patients in the control group. An accompanying editorial to Dixon’s article advocated that the treatment for diabetes be reshaped to include consideration of surgical therapy as an option for patients, especially severely obese patients.

Despite these data in the literature, there has been resistance from endocrinologists and internists specializing in the medical treatment of diabetes to accept the use of surgical therapy as an optimal treatment for the disease. One major criticism pertaining to the quality of outcome studies for diabetes surgery has been that except for the Dixon study, none have been randomized controlled trials. In the last few years, however, three additional randomized controlled trials have been published in high-impact medical journals. Schauer and colleagues (n = 150) showed superior glycemic control (defined as hemoglobin A1c [HbA1c] <6% with or without medications) after RYGB (42%) and SG (37%) compared to intensive medical therapy (12%) at 1 year (P < .001) in patients with mild to moderate obesity (BMI 27–43 kg/m²) and poorly controlled T2DM (average HbA1c 9%). Gastric bypass and SG resulted in greater improvement in other cardiovascular risk factors such as BMI, triglycerides, high-density lipoprotein, and C-reactive protein compared with intensive medical therapy. The surgical patients also significantly reduced their dependency on diabetes medications, while medical patients had increased dependency on diabetes medications. Mingrone and colleagues (n = 60) demonstrated that diabetes remission rates (HbA1c <6.5% without medications) were superior after BPD (95%) and RYGB (75%) compared to conventional medical therapy (0%) at 2 years (P < .001) in patients with severe obesity (average BMI 45 kg/m²) and poorly controlled T2DM (average HbA1c 9%). All four randomized controlled trials to date have shown that surgery in the short term (1–2 years) was well tolerated, with few major complications (two serious cases of sepsis), no cardiovascular events, and no operative mortality, and that surgery resulted in both superior glycemic control and greater improvements in cardiovascular risk factors compared to medical treatment alone.

Adoption of metabolic surgery by endocrinologists, internists, and primary care physicians as a treatment of T2DM has gradually increased over the last 5 years. The Diabetes Surgery Summit in 2007 published the first consensus guidelines for the use and study of metabolic surgery. Since 2009, the American Diabetes Association has included bariatric surgery in their position statement on standards of medical care in T2DM. The guideline indicates that “bariatric surgery should be considered for adults with BMI ≥35 kg/m² and T2DM, especially if the diabetes is difficult to control with lifestyle and pharmacological therapy.” In 2011, the International Diabetes Federation (IDF) released its position statement on the role of surgery and other gastrointestinal interventions in the management of T2DM. At this time, the IDF guidelines are the most useful summaries, from the evidence available, for healthcare providers who manage patients with T2DM. The IDF guidelines are the first to recommend that metabolic surgery be considered for patients with a BMI as low as 30 kg/m² if they are not in good glycemic control on optimal medical therapy.

**Metabolic Syndrome.** The metabolic syndrome is characterized by central obesity, glucose intolerance, dyslipidemia, and hypertension. This is a common finding in patients with severe obesity, occurring in 52% of individuals in one report. All the associated metabolic problems of the metabolic syndrome respond to surgical therapy to produce weight loss. Basic scientists attribute the occurrence of this associated array of diseases to an enhanced inflammatory state in the body resulting from the increased production of cytokines by the adipocyte. These cytokines in turn produce a mild inflammatory reaction that promotes the production of these diseases.

Diabetes and glucose tolerance are effectively treated by bariatric operations as discussed earlier. These operations also are effective in treating the other components of metabolic syndrome.
RYGB produced a 98% resolution of the metabolic syndrome in patients 1 year after surgery.\(^1\)

Dyslipidemias improve in over 70% of patients undergoing RYGB. Improvement is 100% and resolution is greater than 90% after any of the malabsorptive operations (see Table 27-7). Overall lipid profiles are improved, and the degree to which this occurs is in part related to exercise levels of the individual as well as genetic components of the disease.

**Cardiovascular Disease.** Hypertension, a component of the metabolic syndrome, is one of the cardiovascular diseases that are increased in the setting of obesity. Elevated arterial pressure in patients with obesity-related hypertension is associated with increased cardiac output and total peripheral resistance. The elevated output is related to expanded intravascular volume that increases cardiopulmonary volume, venous return, and left ventricular preload; the elevated pressure and total peripheral resistance increase afterload. This dual ventricular overload promotes arrhythmias, concentric cardiac hypertrophy in response to the volume and pressure overload. Increased myocardial oxygen demand results from the elevated tension in the left ventricular wall, reflecting its increased diameter and pressure, and provides a physiologic rationale for the greater potential of coronary arterial insufficiency and cardiac failure. There is greater renal blood flow and lower renal vascular resistance in patients with obesity-related hypertension at any level of arterial pressure. This may be offset by an increased renal filtration fraction that may favor protein deposition and glomerulosclerosis.\(^2\)

Weight loss results in decreased intravascular volume, decreased cardiac output, and decreased arterial pressure. These manifestations occur after all the various bariatric operations that produce weight loss.

Heart failure also is increased in the setting of severe obesity. Much of the risk is secondary to the processes mentioned earlier, which produce hypertension and cardiac hypertrophy. Hypertension and obesity have significant independent associations with left ventricular hypertrophy and cardiac wall thickness. Obesity is particularly strongly associated with left ventricular internal diameter.\(^3\)

Much data now exists regarding the effect of bariatric surgery on cardiovascular disease. A recent systematic review of long-term cardiovascular risk factor reduction after bariatric surgery involved 73 studies and 19,543 subjects with a mean age of 42 years; 76% of subjects were female, and 44%, 24%, and 44% had a baseline hypertension, diabetes, and hyperlipidemia, respectively.\(^4\) At a mean follow-up of 57.8 months, the average excess weight loss for all bariatric procedures was 54%, and remission/improvement was 63% for hypertension, 73% for T2DM, and 65% for hyperlipidemia. Echocardiographic results from 713 subjects showed statistically significant improvements in left ventricular mass, E/A ratio, and isovolumic relaxation time postoperatively.

Thus far, there are no long-term randomized controlled trials comparing bariatric surgery with nonsurgical medical treatment of obesity that evaluate cardiovascular endpoints and mortality. However, 12 cohort-matched studies comparing bariatric surgery with nonsurgical controls have recently been reviewed.\(^5\) Collectively, all but two of these studies support a reduced cardiovascular event rate and all-cause mortality rate conferred by bariatric surgery. Of these studies, the Swedish Obesity Subjects (SOS) study has the longest outcomes follow-up at a median of 14.7 years.\(^6\) Cardiovascular mortality in the surgical group was significantly lower than for control subjects (adjusted hazard ratio, 0.47; 95% confidence interval, 0.29–0.76; \(P < .002\)) despite the greater prevalence of smoking and higher baseline weights and blood pressures in the surgical cohort. The SOS study has formed the basis of much of our current understanding of medium- and long-term outcomes after bariatric surgery despite the fact that the majority of their surgical cohort received vertical-banded gastroplasty (>70%), a gastric volume reduction procedure that is now rarely performed in the United States.

**Resolution of Other Comorbid Medical Problems**

Bariatric surgery can produce resolution of many, if not all, of the comorbid medical problems associated with obesity and present at the time of surgery. This is true to some extent for all bariatric procedures, although some are more efficient at reversing specific comorbid problems than others.

GERD is symptomatically present in approximately half of patients with severe obesity and has been objectively proven to be present in 21%.\(^7\) Unfortunately, obese patients with GERD have a higher chance of failing to obtain symptomatic relief from standard antireflux surgery. The recurrence of symptoms is higher, likely due to a higher incidence of wrap herniation into the mediastinum and other mechanical failure of the fundoplication, which in turn is likely affected by the increased intra-abdominal pressure of the obese condition. The patient with a BMI over 35 kg/m\(^2\) who has GERD has a better chance of elimination of symptoms by undergoing LRYGB, which is >90% effective in the elimination of GERD.\(^8\) LRYGB creates such a small gastric pouch that it has a very limited volume for acid production. LAGB improves GERD but to a considerably lesser extent than RYGB. A recent prospective analysis of 558 consecutive laparoscopic SG (\(n = 200\)) and LRYGB (\(n = 358\)) patients demonstrated significantly improved subjective GERD symptoms in the bypass cohort when compared to the SG patients at 1 year (\(P < .001\)).\(^9\) In fact, some studies suggest that SG can increase GERD symptoms postoperatively. Zhang and colleagues\(^\text{10}\) reported new reflux seen on upper gastrointestinal series in 18% of their 28 patients after SG.

OSA is a disturbance of sleep associated with obesity. It is a measurable problem, quantitated by polysomnography. In one recent study of 349 patients considering bariatric surgery who were referred and tested, only 17% had no sleep apnea, whereas 32% had mild, 18% moderate, and 33% severe sleep apnea.\(^\text{11}\) At a mean time of 11 months after RYGB, the mean Respiratory Disturbance Index for all patients decreased from 51 to 15 (\(P < 0.01\)). Of 83 patients using continuous positive airway pressure or bilevel positive airway pressure preoperatively, only 31 still required it, and they had decreased setting requirements. A recent systematic review of 13,900 patients (69 studies) showed significant improvement or resolution of sleep apnea in more than 75% of bariatric surgery patients.\(^\text{12}\) Comparison of outcomes between procedures demonstrated the most benefit with BPD and gastric bypass and the least with LAGB. However, a recent randomized control trial comparing the effect of medical and surgical weight loss (LAGB) on sleep apnea found no significant difference in apnea events despite major differences in weight loss. The findings suggested that much of the improvement achieved was in the mild to moderate weight loss range, with little benefit of further weight loss.\(^\text{13}\)

Another pulmonary symptom that commonly occurs in severely obese patients is asthma. Dixon and colleagues\(^\text{14}\) studied 23 asthmatic patients who underwent bariatric surgery and found a significant improvement in asthma control (e.g., forced expiratory
volume in 1 second, forced vital capacity), asthma-related quality of life, and responsiveness to methacholine. Boulet and colleagues found similar results in their cohort of 12 patients with asthma who experienced significant weight loss after bariatric surgery.

Nonalcoholic fatty liver disease (NAFLD) is a metabolically related problem associated with obesity. The disease is a spectrum of liver abnormalities including steatosis, steatohepatitis, fibrosis, and cirrhosis of the liver. It is estimated that 20% of U.S. adults have NAFLD, largely because of the high incidence of obesity. NAFLD is present in an estimated 85% of patients with severe obesity. Due to the high incidence of this disease, some authorities have advocated routine liver biopsy at the time of bariatric operations. However, since the treatment of the disease is weight loss, patients with mild forms of the disease need no further treatment or follow-up. Biopsy reports showing any degree of fibrosis should be further followed up by a hepatologist. Weight loss after RYGB decreases metabolic disease, hepatic steatosis, inflammation, and in some cases even fibrosis. Although further research is needed to accurately assess the role of bariatric surgery as a potential treatment for NAFLD, there are numerous reports that support its use. A recent systematic review of the available literature found many retrospective and prospective observational cohort studies, but no randomized control trials or case-control series. There did appear to be significant histologic regression of NAFLD in most of these studies; however, steatohepatitis and fibrosis were also observed in rare cases postoperatively. In one prospective study with before and after liver biopsies, residual steatohepatitis did not appear to be associated with the various bariatric approaches; rather, it was related to higher baseline BMI, degree of previous steatosis/fibrosis, NAFLD activity score, ballooning, degree of inflammation, and insulin resistance. The role of bariatric surgery in the treatment of NAFLD remains to be seen.

Musculoskeletal problems, especially degenerative joint disease and low back pain, are among the most common complaints and associated comorbid problems of the severely obese population. Quantitation of their severity, however, is often difficult, making resolution or improvement equally difficult. Symptoms often resolve and usually improve in patients who experience significant weight loss. This is likely a combined effect of the direct lessened work load as well as some secondary resolution of the inflammatory process of the joints brought on directly and indirectly by obesity. A prospective cohort of 50 obese females age 20 to 74 years were followed for 1 year after RYGB using the timed-get-up-and-go (TGUG) and health survey short form-36 (SF-36). The results showed a significant improvement in musculoskeletal function and likely enhanced ability to progress in rehabilitation. Patients with osteoarthritis of the neck, shoulder, spine, hip, knee, ankle, wrist, and hand have been shown to have improved or resolved joint pain after bariatric surgery. Reduction in BMI values of 6.2 to 14.7 kg/m² has corresponded with back and knee pain resolution in 5% to 100% of patients, whereas pain severity was reduced in 31% to 94% of patients depending on the joint and study.

**Plastic Surgery after Weight Loss**

Patients who have undergone bariatric surgery are often left with large amounts of hanging skin or rolls of skin and subcutaneous tissue as a result of the weight loss. Additional problems include skin rashes; maceration under folds in the pannus, thighs, and breasts; body odor; and poorly fitting clothes. Excess skin can be a limiting factor in exercise and sexual activity.

Many patients desire to be rid of the extra skin and its associated problems. The major problem they face, however, in accomplishing this is obtaining insurance approval for surgical removal of the excess skin. Most insurance companies consider this “cosmetic” surgery and will not authorize coverage. A few, with appropriate documentation of the conditions and problems from excess skin, do provide coverage for surgery. Plastic surgeons who are experienced in abdominoplasty and body contouring can offer these patients an excellent surgical treatment for the problems of excessive skin.

Reconstructive surgery requires careful preoperative planning and is based on the patient’s deformities and priorities. Excess tissue of the lower torso is the most common deformed area for which patients undergo surgical intervention. A standard abdominoplasty to remove this excessive tissue is performed. More radical body contouring can include a circumferential abdominoplasty and lower body lift. This procedure involves excision of tissue from the buttocks and lateral thighs, with skin undermining down the thighs. Circumferential abdominoplasty removes redundant skin of the lower abdomen, flattens the abdomen, and incorporates the lower body lift. It requires central undermining to the xiphoid and minimal lateral undermining of the superior flap. The central abdominal fascia often requires imbrication. If simultaneous abdominal hernia repair is performed, this performs the function of fascial imbrication by creating a repair with some degree of fascial tension. The closure of the superior flap to the inferior skin edge incorporates lateral tension to narrow the waist and advance the anterolateral thighs. Medial thighplasty also may be needed for patients with significant excess medial thigh skin. This is done transversely.

Excess skin redundancy distal to the mid-thighs requires long vertical medial excision of skin. Mid-back and epigastric rolls, along with sagging breasts, are corrected with an upper body lift. The upper body lift is a reverse abdominoplasty, removal of mid-torso excessive skin, and reshaping of the breasts. For highly selected individuals, and with a well-organized team, a single-stage total body lift, which includes a circumferential abdominoplasty, lower body lift, medial thighplasty, an upper body lift, and breast reshaping, can be performed safely in under 8 hours (Figs. 27-24 and 27-25). While many bariatric surgery programs do not have the accompanying volume, experience, and interest to offer such an extensive single-stage operation, most programs do offer availability of plastic surgery expertise for abdominoplasty and removal of excess skin of the extremities as separate procedures. Increasing numbers of patients undergoing bariatric surgery have provided an increased flow of patients requesting such services, which in turn should lead to improved outcomes with increasing experience for surgeons performing these procedures. One matched control study suggests that plastic surgery after bariatric surgery may actually improve long-term weight loss.

**Endoscopic, Electric, and Other Experimental Procedures**

Bariatric surgery has been a field of constant succession of procedures in an attempt to improve safety, minimize invasiveness, and offer better outcomes. Recent experimental procedures in electrical stimulation of the stomach and vagus nerves have been performed to produce weight loss.

The implantable gastric stimulation device, initially marketed by Trasneurionix, Inc., in the early part of the twenty-first century, was a dual-lead implantable gastric electrical
Figure 27-24. Preoperative frontal, right lateral, and left anterior oblique views of a 36-year-old, 150-lb, 5’6” woman who lost 120 lb 2 years after laparoscopic Roux-en-Y bypass procedure. She desired a one-stage total body lift and bilateral brachioplasties, which were performed in the manner described in the text. (Courtesy of Dennis Hurwitz, MD, Clinical Professor of Plastic Surgery, University of Pittsburgh.)

stimulator that theoretically interfered with the stomach’s innate myoelectric pattern, causing decreased gastric emptying and nausea. A mean excess weight loss of 23% was reported at 16-month follow-up for the second U.S. trial. Longer-term follow-up for the first European study showed a 25% excess weight loss in 91 patients over a 2-year follow-up. The disappointing aspect of this treatment is that a significant number of the patients lose little weight, whereas a smaller group seem to respond well to the treatment. The ability to select patients who will respond remains a challenge for this technology, which is still in the status of only a proposed potential operation for weight loss.

Figure 27-25. Frontal, right lateral, and left anterior oblique views 6 weeks after surgery for the woman in Fig. 27-24. The scars indicate the circumferential abdominoplasty, lower body lift, upper body lift, breast reshaping, and autoaugmentation through a keyhole pattern and bilateral brachioplasties. All redundant skin has been removed, leaving well-positioned scars and feminine features. (Courtesy of Dennis Hurwitz, MD, Clinical Professor of Plastic Surgery, University of Pittsburgh.)
Vagal stimulation/blockade has recently been proposed as a means of stimulating the neural input to the stomach to achieve decrease in appetite, early satiety, at times nausea, and weight loss. Data to date have been sparse and very preliminary in showing any merits of the potential efficacy of this approach.118

Endoscopic procedures to decrease gastric pouch size and to limit gastrojejunoanostomy anastomotic size are currently being performed at several medical centers.84,119 These are currently reoperative procedures, not initial procedures for weight loss. Long-term weight loss of significant magnitude has yet to be demonstrated by these revisional endoscopic procedures.

Intragastric balloon placement has resurfaced on the bariatric scene in the past few years. The Garren-Edwards bubble of the late 1980s era196 was prone to migration and bowel obstruction, which led to its early demise. Now this concept has resurfaced as a short-term bridge to weight loss to be followed by a more definitive procedure. While there may be some limited application of this device for such purposes,107 its ability to produce durable weight loss is unproven. It may have potential use only as a preliminary procedure prior to a more definitive one.

Prototype procedures undergoing trial include one that uses an endoscopically placed sleeve to limit absorption. A small randomized control study out of the Netherlands compared an endoscopically placed intraluminal sleeve extending from the duodenum to the jejunum (EndoBarrier) to a diet modification group.118 They successfully placed 26 devices, but were unable to do so in 4 cases. Four implants had to be removed before the end of the study due to migration, obstruction, and continuous epigastric pain. Mean weight loss at 3 months was 19.0% in the study group and 6.9% in the control group. HbA1c was significantly improved after EndoBarrier placement in seven of eight patients with T2DM. An FDA trial is currently under way to determine the long-term safety and efficacy of this experimental gastrointestinal liner.

The eventual ability to endoscopically create a stapled or sutured gastric pouch and hence a completely endoscopically performed restrictive operation is being envisioned. While these proposed procedures speak to the energy and innovation of today’s bariatric surgery community, their implementation into clinical practice has yet to occur. Endoscopic procedures and devices such as the transoral gastroplasty (TOGA) and the transoral endoscopic restrictive implant system (TERIS) did not initially achieve sufficient weight loss to satisfy FDA requirements and thus have been withheld from further development at this time.199,200

Other investigational procedures under development and performed laparoscopically include the duodenal-jejunal bypass and ileal transposition. These procedures are intended to improve T2DM without intentional weight loss.201,202 Gastrectomy is also a new laparoscopic procedure intended to mimic results of SG but without requiring stapling or stomach removal.203 Further studies with long-term safety and efficacy data are required before these investigational procedures can be considered for routine clinical use.

**Introduction**

The small intestine is the raison d’être of the gastrointestinal tract as it is the principle site of nutrient digestion and absorption. The small intestine is also the body’s largest reservoir of immunologically active and hormone-producing cells and hence can be conceptualized as the largest organ of the immune and endocrine systems, respectively. It achieves this diversity of action through unique anatomic features, which provide it with a massive surface area, a diversity of cell types, and a complex neural network to coordinate these functions.

Despite its size and importance, diseases of the small intestine are relatively infrequent and present diagnostic and therapeutic challenges. Treatments for common conditions such as postoperative ileus are hardly more effective than those used at the dawn of the last century. Mortality rates associated with acute mesenteric ischemia have not improved during the past 50 years.

**Gross Anatomy**

The small intestine is a tubular structure that extends from the pylorus to the cecum. The estimated length of this structure varies depending on whether radiologic, surgical, or autopsy measurements are made. In the living, it is thought to measure 4 to 6 m. The small intestine consists of three segments lying in series: the duodenum, the jejunum, and the ileum.

Despite introduction of novel imaging techniques such as capsule endoscopy and double balloon endoscopy, diagnostic tests lack sufficient predictive power to definitively guide clinical decision making for individual patients. Furthermore, few high-quality, controlled data on the efficacy of surgical therapies for small bowel diseases are available.

Therefore, sound clinical judgment and a thorough understanding of anatomy, physiology, and pathophysiology remain essential to the care of patients with intestinal disorders.
The small intestine performs a diverse set of functions. Small bowel obstruction is one of the most common surgical diagnoses. Most cases of small bowel obstruction are due to adhesions from previous surgery and resolve with conservative management. Tumors and malignancies of the small bowel are rare and difficult to diagnose.

Small bowel may be the source of gastrointestinal bleeding, which may be difficult to diagnose. If following surgical resection, less than 200 cm of small bowel remains, patients are at risk of developing short bowel syndrome.

The duodenum, the most proximal segment, lies in the retroperitoneum immediately adjacent to the head and inferior border of the body of the pancreas. The duodenum is demarcated from the stomach by the pylorus and from the jejunum by the ligament of Treitz. The jejunum and ileum lie within the peritoneal cavity and are tethered to the retroperitoneum by a broad-based mesentery. No distinct anatomic landmark demarcates the jejunum from the ileum; the proximal 40% of the jejun ileal segment is arbitrarily defined as the jejunum and the distal 60% as the ileum. The ileum is demarcated from the cecum by the ileocecal valve.

The small intestine contains internal mucosal folds known as plicae circulares or valvulae conniventes that are visible upon gross inspection. These folds are also visible radiographically and help in the distinction between small intestine and colon, which does not contain them, on abdominal radiographs. These folds are more prominent in the proximal intestine than in the distal small intestine. Other features evident on gross inspection that are more characteristic of the proximal than distal small intestine include larger circumference, thicker wall, less fatty mesentery, and longer vasa recta (Fig. 28-1). Gross examination of the small-intestinal mucosa also reveals aggregates of lymphoid follicles. Those follicles, located in the ileum, are the most prominent and are designated Peyer’s patches.

Most of the duodenum derives its arterial blood from branches of both the celiac and the superior mesenteric arteries. The distal duodenum, the jejunum, and the ileum derive their arterial blood from the superior mesenteric artery. Their venous drainage occurs via the superior mesenteric vein. Lymph drainage occurs through lymphatic vessels coursing parallel to corresponding arteries. This lymph drains through mesenteric lymph nodes to the cisterna chyli, then through the thoracic duct, and ultimately into the left subclavian vein. The parasympathetic and sympathetic innervation of the small intestine is derived from the vagus and splanchnic nerves, respectively.

The jejunum is arbitrarily defined as the jejunum and the distal 60% as the ileum. The ileum is demarcated from the cecum by the ileocecal valve. The jejunum and ileum lie within the peritoneal cavity and are tethered to the retroperitoneum by a broad-based mesentery. No distinct anatomic landmark demarcates the jejunum from the ileum; the proximal 40% of the jejun ileal segment is arbitrarily defined as the jejunum and the distal 60% as the ileum. The ileum is demarcated from the cecum by the ileocecal valve.

The mucosa is organized into villi and crypts (crypts of Lieberkühn). Villi are finger-like projections of epithelium and underlying lamina propria that contain blood and lymphatic (lacteals) vessels that extend into the intestinal lumen. Intestinal, epithelial cellular proliferation is confined to the crypts, each of which carries 250 to 300 cells. All epithelial cells in each crypt are derived from an unknown number of multipotent stem cells located at or near the crypt’s base. Our understanding of these crypt cells is rapidly expanding. It appears that there are two subgroups of intestinal stem cells, with specific cell markers. Bmi1-positive cells are usually quiescent, radiation-resistant cells that are induced by injury, whereas LGR5-positive cells facilitate homeostatic vs. injury-induced regeneration and are radiation sensitive.

The stem cells can differentiate along one of four pathways that ultimately yield enterocytes and goblet, enteroendocrine, and Paneth cells. With the exception of Paneth cells, these lineages complete their terminal differentiation during an upward migration from each crypt to adjacent villi. The journey from the crypt to the villus tip is completed in 2 to 5 days and terminates with cells being removed by apoptosis and/or exfoliation. Thus, the small-intestinal epithelium undergoes exfoliation.

Figure 28-1. Gross features of jejunum contrasted with those of ileum. Relative to the ileum, the jejunum has a larger diameter, a thicker wall, more prominent plicae circulares, a less fatty mesentery, and longer vasa recta.
continuous renewal, making it one of the body’s most dynamic tissues. The high cellular turnover rate contributes to mucosal resiliency but also makes the intestine uniquely susceptible to certain forms of injury such as that induced by radiation and chemotherapy.

Enterocytes are the predominant absorptive cell of the intestinal epithelium. Their apical (lumen-facing) cell membrane contains specialized digestive enzymes, transporter mechanisms, and microvilli that are estimated to increase the absorptive surface area of the small intestine by up to 40-fold. Goblet cells produce mucin believed to play a role in mucosal defense against pathogens. Enteroendocrine cells are characterized by secretory granules containing regulatory agents and are discussed in greater detail later in the Endocrine Function section. Paneth cells are located at the base of the crypt and contain secretory granules containing growth factors, digestive enzymes, and antimicrobial peptides. In addition, the intestinal epithelium contains M cells and intraepithelial lymphocytes. These two components of the immune system are discussed later.

The submucosa consists of dense connective tissue and a heterogeneous population of cells, including leukocytes and fibroblasts. The submucosa also contains an extensive network of vascular and lymphatic vessels, nerve fibers, and ganglion cells of the submucosal (Meissner’s) plexus.

The muscularis propria consists of an outer, longitudinally oriented layer and an inner, circularly oriented layer of smooth muscle fibers. Located at the interface between these two layers are ganglion cells of the myenteric (Auerbach’s) plexus.

The serosa consists of a single layer of mesothelial cells and is a component of the visceral peritoneum.

**DEVELOPMENT**

The first recognizable precursor of the small intestine is the embryonic gut tube, formed from the endoderm during the fourth week of gestation. The gut tube is divided into foregut, midgut, and hindgut. Other than duodenum, which is a foregut structure, the rest of the small intestine is derived from the midgut. The gut tube initially communicates with the yolk sac; however, the communication between these two structures narrows by the sixth week to form the vitelline duct. The yolk sac and vitelline duct usually undergo obliteration by the end of gestation. Incomplete obliteration of the vitelline duct results in the spectrum of defects associated with Meckel’s diverticulum.

Also during the fourth week of gestation, the mesoderm of the embryo splits. The portion of mesoderm that adheres to the endoderm forms the visceral peritoneum, while the portion that adheres to the ectoderm forms the parietal peritoneum. This mesodermal division results in the formation of a coelomic cavity that is the precursor of the peritoneal cavity.

At approximately the fifth week of gestation, the bowel begins to lengthen to an extent greater than that which can be accommodated by the developing abdominal cavity, resulting in the extracoelomic herniation of the developing bowel. The bowel continues to lengthen during the subsequent weeks and is retracted back into the abdominal cavity during the tenth week of gestation. Subsequently, the duodenum becomes a retroperitoneal structure. Coincident with extrusion and retraction, the bowel undergoes a 270° counterclockwise rotation relative to the posterior abdominal wall. This rotation accounts for the usual locations of the cecum in the right lower quadrant and the duodenojejunal junction to the left of midline (Fig. 28-3).

The celiac and superior mesenteric arteries and veins are derived from the vitelline vascular system, which in turn is derived from blood vessels formed within the splanchnopleuric mesoderm during the third week of gestation. Neurons found in the small intestine are derived from neural crest cells that begin to migrate away from the neural tube during the third week of gestation. These neural crest cells enter the mesenchyme of the primitive foregut and subsequently migrate to the remainder of the bowel.

During the sixth week of gestation, the lumen of the developing bowel becomes obliterated as bowel epithelial proliferation accelerates. Vacuoles form within the bowel substance during the subsequent weeks and coalesce to form the intestinal lumen by the ninth week of gestation. Errors in this recanalization may account for defects such as intestinal webs and stenoses. Most intestinal atresias, however, are believed to be related to ischemic episodes occurring after organogenesis has been completed rather than to errors in recanalization.

During the ninth week of gestation, the intestinal epithelium develops intestine-specific features such as crypt-villus architecture. Organogenesis is complete by approximately the twelfth week of gestation.

**Figure 28-2.** Layers of wall of the small intestine. The individual layers and their prominent features are represented schematically.
**Physiology**

**Digestion and Absorption**

The intestinal epithelium is the interface through which absorption and secretion occur. It has features characteristic of absorptive epithelia in general including epithelial cells with cellular membranes possessing distinct apical (luminal) and basolateral (serosal) domains demarcated by intercellular tight junctions and an asymmetric distribution of transmembrane transporter mechanisms that promotes vectorial transport of solutes across the epithelium.

Solute can traverse the epithelium by active or passive transport. Passive transport of solutes occurs through diffusion or convection and is driven by existing electrochemical gradients. Active transport is the energy-dependent net transfer of solutes in the absence of or against an electrochemical gradient.

Active transport occurs through transcellular pathways (through the cell), whereas passive transport can occur through either transcellular or paracellular pathways (between cells through the tight junctions). Transcellular transport requires solutes to traverse the cell membranes through specialized membrane proteins, such as channels, carriers, and pumps. The molecular characterization of transporter proteins is evolving rapidly, with different transporter families, each containing many individual genes encoding specific transporters, now identified.

Similarly, understanding of the paracellular pathway is evolving. In contrast to what was once believed, it is becoming apparent that paracellular permeability is substrate-specific, dynamic, and subject to regulation by specific tight junction proteins.

**Water and Electrolyte Absorption and Secretion.** Eight to nine L of fluid enters the small intestine daily. Most of this volume consists of salivary, gastric, biliary, pancreatic, and intestinal secretions. Under normal conditions, the small intestine absorbs over 80% of this fluid, leaving approximately 1.5 L that enters the colon (Fig. 28-4). Small-intestinal absorption and secretion are tightly regulated; derangements in water and electrolyte homeostasis characteristic of many of the disorders discussed in this chapter play an important role in contributing to their associated clinical features.
Carbohydrate Digestion and Absorption. Approximately 45% of energy consumption in the average Western diet consists of carbohydrates, approximately one half of which is in the form of starch (linear or branched polymers of glucose) derived from cereals and plants. Other major sources of dietary carbohydrates include sugars derived from milk (lactose), fruits and vegetables (fructose, glucose, and sucrose), or purified from sugar cane or beets (sucrose). Processed foods contain a variety of sugars including fructose, oligosaccharides, and polysaccharides. Glycogen derived from meat contributes only a small fraction of dietary carbohydrate.

Pancreatic amylase is the major enzyme of starch digestion, although salivary amylase initiates the process. The terminal products of amylase-mediated starch digestion are oligosaccharides, maltotriose, maltose, and α-limit dextrins (Fig. 28-6). These products, as well as the major disaccharides (Fig. 28-6). These products, as well as the major disaccharides in the diet (sucrose and lactose), are unable to undergo absorption in this form. They must first undergo hydrolytic cleavage into their constituent monosaccharides; these hydrolytic reactions are catalyzed by specific brush border membrane hydrolases that are expressed most abundantly in the villi of the duodenum and jejunum. The three major monosaccharides that represent the terminal products of carbohydrate digestion are glucose, galactose, and fructose.

Under physiologic conditions, most of these sugars are absorbed through the epithelium via the transcellular route. Glucose and galactose are transported through the enterocyte brush border membrane via intestinal Na+-glucose cotransporter, SGLT1 (Fig. 28-7). Fructose is transported through the brush border membrane by facilitated diffusion via GLUT5 (a member of the facilitative glucose transporter family). All three monosaccharides are extruded through the basolateral membrane by facilitated diffusion using GLUT2 and GLUT5 transporters. Extruded monosaccharides diffuse into venules and ultimately enter the portal venous system.

There is evidence of overexpression of hexose transporters, specifically SGLT1, in disease states such as diabetes. Several approaches aimed at downregulation of intestinal glucose transporter are being investigated as a novel therapy for disease states such as diabetes and obesity.

Protein Digestion and Absorption. Ten to fifteen percent of energy consumption in the average Western diet consists of proteins. In addition to dietary proteins, approximately one half of the protein load that enters the small intestine is derived from
endogenous sources including salivary and gastrointestinal secretions and desquamated intestinal epithelial cells. Protein digestion begins in the stomach with action of pepsins. This is not, however, an essential step, since surgical patients who are achlorhydric or who have lost part or all their stomach are still able to successfully digest proteins. Digestion continues in the duodenum with the actions of a variety of pancreatic peptidases.

**Figure 28-6.** Carbohydrate digestion. Dietary carbohydrates, including starch and the disaccharides sucrose and lactose, must undergo hydrolysis into constituent monosaccharides glucose, galactose, and fructose before being absorbed by the intestinal epithelium. These hydrolytic reactions are catalyzed by salivary and pancreatic amylase and by enterocyte brush border hydrolases.

These enzymes are secreted as inactive proenzymes. This is in contrast to pancreatic amylase and lipase, which are secreted in their active forms. In response to the presence of bile acids, enterokinase is liberated from the intestinal brush border membrane to catalyze the conversion of trypsinogen to active trypsin; trypsin in turn activates itself and other proteases. The final products of intraluminal protein digestion consist of neutral and basic amino acids and peptides two to six amino acids in length (Fig. 28-8). Additional digestion occurs through the actions of peptidases that exist in the enterocyte brush border and cytoplasm. Epithelial absorption occurs for both single amino acids and di- or tripeptides via specific membrane-bound transporters. Absorbed amino acids and peptides then enter the portal venous circulation.

Of all amino acids, glutamine appears to be a unique, major source of energy for enterocytes. Active glutamine uptake into enterocytes occurs through both apical and basolateral transport mechanisms.

**Fat Digestion and Absorption.** Approximately 40% of the average Western diet consists of fat. Over 95% of dietary fat is in the form of long-chain triglycerides; the remainder includes phospholipids such as lecithin, fatty acids, cholesterol, and fat-soluble vitamins. Over 94% of the ingested fats are absorbed in the proximal jejunum.

Since fats are normally water insoluble, key to successful digestion of ingested fats is solubalization of them into an emulsion by the mechanical actions of mastication and antral peristalsis. Although lipolysis of triglycerides to form fatty acids and monoglycerides is initiated in the stomach by gastric lipase, its principal site is the proximal intestine, where pancreatic lipase is the catalyst (Fig. 28-9).
Absorbed portal venous blood. Most lipids are absorbed in the proximal intestine, undergoing intraluminal hydrolysis, micellar solubilization, and then absorption by the intestinal epithelium directly, without undergoing lipolysis, and are secreted into the portal venous circulation.

**Triglycerides**
- Resynthesized in enterocytes
- Absorbed
- Chyle (lymphatics)
- Portal venous blood

**Fat digestion.** Long-chain triglycerides, which constitute the majority of dietary fats, must undergo lipolysis into constituent long-chain fatty acids and monoglycerides before being absorbed by the intestinal epithelium. These reactions are catalyzed by gastric and pancreatic lipases. The products of lipolysis are transported in the form of mixed micelles to enterocytes, where they are resynthesized into triglycerides, which are then packaged in the form of chylomicrons that are secreted into the intestinal lymph (chyle). Triglycerides composed of short- and medium-chain fatty acids are absorbed by the intestinal epithelium directly, without undergoing lipolysis, and are secreted into the portal venous circulation.

**Figure 28-9.**

Dietary long-chain triglycerides → Gastric lipase → Pancreatic lipase → Long-chain fatty acids and monoglycerides → Absorbed triglycerides → Resynthesized in enterocytes → Chyle (lymphatics) → Portal venous blood

Bile acids act as detergents that help in solubilization of the lipolysis by forming mixed micelles. These micelles are polymolecular aggregates with a hydrophobic core of fat and a hydrophilic surface that act as shuttles, delivering the products of lipolysis to the enterocyte brush border membrane, where they are absorbed. The bile salts, however, remain in the bowel lumen and travel to the terminal ileum, where they are actively resorbed. They enter the portal circulation and are resecreted into bile, thus completing the enterohepatic circulation.

Dissociation of lipids from the micelles occurs in a thin layer of water (50–500 μm thick) with an acidic microenvironment immediately adjacent to the brush border called the **unstirred water layer**. Most lipids are absorbed in the proximal jejunum, whereas bile salts are absorbed in the distal ileum through an active process. Fatty acid binding proteins (FABPs) are a family of proteins located on the brush border membrane, facilitating diffusion of long-chain fatty acids across the brush border membrane. Cholesterol crosses the brush border membrane through an active process that is yet to be completely characterized. Within the enterocytes, triglycerides are resynthesized and incorporated into chylomicrons that are secreted into the intestinal lymphatics and ultimately enter the thoracic duct. In these chylomicrons, lipoproteins serve a detergent-like role similar to that served by bile salts in the mixed micelles.

The steps described above are required for the digestion and absorption of triglycerides containing long-chain fatty acids. However, triglycerides containing short- and medium-chain fatty acids are more hydrophilic and are absorbed without undergoing intraluminal hydrolysis, micellar solubilization, mucosal re-esterification, and chylomicron formation. Instead, they are directly absorbed and enter the portal venous circulation rather than the lymphatics. This information provides the rationale for administering nutritional supplements containing medium-chain triglycerides to patients with gastrointestinal diseases associated with impaired digestion and/or malabsorption of long-chain triglycerides.

**Vitamin and Mineral Absorption.** Vitamin B<sub>12</sub> (cobalamin) malabsorption can result from a variety of surgical manipulations. The vitamin is initially bound by saliva-derived R protein. In the duodenum, R protein is hydrolyzed by pancreatic enzymes, allowing free cobalamin to bind to gastric parietal cell–derived intrinsic factor. The cobalamin-intrinsic factor complex is able to escape hydrolysis by pancreatic enzymes, allowing it to reach the terminal ileum, which expresses specific receptors for intrinsic factor. Subsequent events in cobalamin absorption are poorly characterized, but the intact complex probably enters enterocytes through translocation. Because each of these steps is necessary for cobalamin assimilation, gastric resection, gastric bypass, and ileal resection can each result in vitamin B<sub>12</sub> insufficiency.

Other water-soluble vitamins for which specific carrier-mediated transport processes have been characterized include ascorbic acid, folate, thiamine, riboflavin, pantothenic acid, and biotin. Fat-soluble vitamins A, D, and E appear to be absorbed through passive diffusion. Vitamin K appears to be absorbed through both passive diffusion and carrier-mediated uptake.

Calcium is absorbed through both transcellular transport and paracellular diffusion. The duodenum is the major site for transcellular transport; paracellular transport occurs throughout the small intestine. A key step in transcellular calcium transport is mediated by calbindin, a calcium-binding protein located in the cytoplasm of enterocytes. Regulation of calbindin synthesis is the principle mechanism by which vitamin D regulates intestinal calcium absorption. Abnormal calcium levels are increasingly seen in surgical patients who have undergone a gastric bypass. Although usual calcium supplementation is often in the form of calcium carbonate, which is cheap, in such patients with low acid exposure, calcium citrate is a better formulation for supplemental therapy.

Iron and magnesium are each absorbed through both transcellular and paracellular routes. A divalent metal transporter capable of transporting Fe<sup>2+</sup>, Zn<sup>2+</sup>, Mn<sup>2+</sup>, Co<sup>2+</sup>, Cd<sup>2+</sup>, Cu<sup>2+</sup>, and Pb<sup>2+</sup> that has recently been localized to the intestinal brush border may account for at least a portion of the transcellular absorption of these ions.8

**Barrier and Immune Function**

Although the intestinal epithelium allows for the efficient absorption of dietary nutrients, it must discriminate between pathogens and harmless antigens such as food proteins and commensal bacteria, and it must resist invasion by pathogens. Factors contributing to epithelial defense include immunoglobulin A (IgA), mucins, and the relative impermeability of the brush border membrane and tight junctions to macromolecules and bacteria. Recently described factors likely to play important roles in intestinal mucosal defense include antimicrobial peptides such as the defensins.9 The intestinal component of the immune system, known as the gut-associated lymphoid tissue (GALT), contains over 70% of the body’s immune cells.

The GALT is conceptually divided into inductive and effector sites.10 Inductive sites include Peyer’s patches, mesenteric lymph nodes, and smaller isolated lymphoid follicles scattered throughout the small intestine (Fig. 28-10).
Peyer’s patches are macroscopic aggregates of B-cell follicles and intervening T-cell areas found in the lamina propria of the small intestine, primarily the distal ileum. Overlying Peyer’s patches are a specialized epithelium containing microfold (M) cells. These cells possess an apical membrane with microfolds rather than microvilli, which is characteristic of most intestinal epithelial cells. Using transepithelial vesicular transport, M cells transfer microbes to underlying professional antigen-presenting cells (APCs), such as dendritic cells. Dendritic cells, in addition, may sample luminal antigens directly through their dendrite-like processes that extend through epithelial tight junctions. APCs interact with and prime naïve lymphocytes, which then exit through the draining lymphatics to enter the mesenteric lymph nodes where they undergo differentiation. These lymphocytes then migrate into the systemic circulation via the thoracic duct and ultimately accumulate in the intestinal mucosa at effector sites. Alternative induction mechanisms, such as antigen presentation within mesenteric lymph nodes, are also likely to exist.

Effector lymphocytes are distributed into distinct compartments. IgA-producing plasma cells are derived from B cells and are located in the lamina propria. CD4+ T cells are also located in the lamina propria. CD8+ T cells migrate preferentially to the epithelium, but are also found in the lamina propria. These T cells are central to immune regulation; in addition, the CD8+ T cells have potent cytotoxic (CTL) activity. IgA is transported through the intestinal epithelial cells into the lumen, where it exists in the form of a dimer complexed with a secretory component. This configuration renders IgA resistant to proteolysis by digestive enzymes. IgA is believed to both help prevent the entry of microbes through the epithelium and to promote egress of antigens or microbes that have already penetrated into the lamina propria.

It has been increasingly recognized that the gastrointestinal tract is colonized with many bacteria that are essential for health. Communication between the microbiota and the host defense allows for protective immune responses against pathogens while preventing adverse inflammatory responses to harmless commensal microbes, which could lead to chronic inflammatory disorders such as celiac disease and Crohn’s disease.11

Motility
Myocytes of the intestinal muscle layers are electrically and mechanically coordinated in the form of syncytia. Contractions of the muscularis propria are responsible for small-intestinal peristalsis. Contraction of the outer longitudinal muscle layer results in bowel shortening; contraction of the inner circular layer results in luminal narrowing. Contractions of the muscularis mucosa contribute to mucosal or villus motility, but not to peristalsis.

Several distinctive patterns of muscularis propria activity have been observed to occur in the small intestine. These patterns include ascending excitation and descending inhibition in which muscular contraction occurs proximal to a stimulus, such as the presence of a bolus of ingested food, and muscular relaxation occurs distal to the stimulus (Fig. 28-11). These two

---

**Figure 28-10.** Gut-associated lymphoid tissue. Select components of the gut-associated lymphoid tissue (GALT) are schematically represented. Peyer’s patches consist of a specialized follicle-associated epithelium (FAE) containing M cells, a subepithelial dome (SED) rich in dendritic cells, and B-cell follicle-containing germinal centers (GC). Plasma cells in the lamina propria produce immunoglobulin A (IgA), which is transported to the intestinal lumen where it serves as the first line of defense against pathogens. Other components of GALT include isolated lymphoid follicles, mesenteric lymph nodes, and regulatory and effector lymphocytes.

**Figure 28-11.** Ascending excitation and descending inhibition. The presence of a food bolus within the intestinal lumen is sensed by a sensory neuron (SN) that relays signals to (a) excitatory motor neurons (EMN) that have projections to intestinal muscle cells located proximal to the food bolus and (b) inhibitory motor neurons (IMN) that have projections to intestinal muscle cells located distal to the food bolus. This stereotypical motor reflex is controlled by the enteric nervous system and occurs in the absence of extraintestinal innervations. It contributes to peristalsis.
reflexes are present even in the absence of any extrinsic innervation to the small intestine and contribute to peristalsis when they are propagated in a coordinated fashion along the length of the intestine. The fed or postprandial pattern begins within 10 to 20 minutes of meal ingestion and abates 4 to 6 hours afterward. Rhythmic segmentations or pressure waves traveling only short distances also are observed. This segmenting pattern is hypothesized to assist in mixing intraluminal contents and in facilitating their contact with the absorptive mucosal surface. The fasting pattern or interdigestive motor cycle (IDMC) consists of three phases. Phase I is characterized by motor quiescence, phase II by seemingly disorganized pressure waves occurring at submaximal rates, and phase III by sustained pressure waves occurring at maximal rates. This pattern is hypothesized to expel residual debris and bacteria from the small intestine. The median duration of the IDMC ranges from 90 to 120 minutes. At any given time, different portions of the small intestine can be in different phases of the IDMC.

The regulatory mechanisms driving small-intestinal motility consist of both pacemakers intrinsic to the small intestine and external neurohumoral modulatory signals. The interstitial cells of Cajal are pleomorphic mesenchymal cells located within the muscularis propria of the intestine that generate the electrical slow wave (basic electrical rhythm or pacemaker potential) that plays a pacemaker role in setting the fundamental rhythmicity of small-intestinal contractions. The frequency of the slow wave varies along the longitudinal axis of the intestine: it ranges from 12 waves per minute in the duodenum to 7 waves per minute in the distal ileum. Smooth muscle contraction occurs only when an electrical action potential (spike burst) is superimposed on the slow wave. Thus, the slow wave determines the maximum frequency of contractions; however, not every slow wave is associated with a contraction.

This intrinsic contractile mechanism is subject to neural and hormonal regulation. The enteric nervous system (ENS) provides both inhibitory and excitatory stimuli. The predominant excitatory transmitters are acetylcholine and substance P, and the inhibitory transmitters include nitric oxide, vasoactive intestinal peptide, and adenosine triphosphate. In general, the sympathetic motor supply is inhibitory to the ENS; therefore, increased sympathetic input into the intestine leads to decreased intestinal smooth muscle activity. The parasympathetic motor supply is more complex, with projections to both inhibitory and excitatory ENS motor neurons. Correspondingly, the effects of parasympathetic inputs into intestinal motility are more difficult to predict.

**Endocrine Function**

Endocrinology as a discipline was born with the discovery of secretin, an intestinal regulatory peptide that was the first hormone to be identified. Our improving understanding of the physiology of the small intestine has lead to identification of many additional intestinal-derived hormones that make this the largest hormone-producing organ in the body. Over 30 peptide hormone genes have been identified as being expressed in the gastrointestinal tract. Because of differential posttranscriptional and posttranslational processing, over 100 distinct regulatory peptides are produced. In addition, monoamines, such as histamine and dopamine, and eicosanoids with hormone-like activities are produced in the intestine.

“Gut hormones” were previously conceptualized as peptides produced by the enteroendocrine cells of the intestinal mucosa that are released into the systemic circulation to reach receptors in target sites in the gastrointestinal tract. Now it is clear that “gut hormone” genes are widely expressed throughout the body, not only in endocrine cells, but also in central and peripheral neurons. The products of these genes are general intercellular messengers that can act as endocrine, paracrine, autocrine, or neurocrine mediators. Thus, they may act as true blood-borne hormones as well as through local effects.

There are notable homology patterns among individual regulatory peptides found in the gastrointestinal tract. Based on these homologies, approximately one half of the known regulatory peptides can be classified into families. For example, the secretin family includes secretin, glucagon, and glucagon-like peptides, glucose-dependent insulinotropic peptide, vasoactive intestinal polypeptide, peptide histidine isoleucine, growth hormone–releasing hormone, and pituitary adenyl cyclase–activating peptide. Other peptide families include those named for insulin, epidermal growth factor, gastrin, pancreatic polypeptide, tachykinin, and somatostatin.

Receptor subtype multiplicity and cell-specific expression patterns for these receptor subtypes that are characteristic of these regulatory mediators make definition of their actions complex. Detailed description of these actions is beyond the scope of this chapter; however, examples of regulatory peptides produced by enteroendocrine cells of the small-intestinal epithelium and their most commonly ascribed functions are summarized in Table 28-2. Some of these peptides, or their analogues, are used in routine clinical practice. For example, therapeutic applications of octreotide, a long-acting analogue of somatostatin, include the amelioration of symptoms associated with neuroendocrine tumors (e.g., carcinoid syndrome), postgastrectomy dumping syndrome, enterocutaneous fistulas, and the initial treatment of acute hemorrhage due to esophageal varices. The gastrin secretory response to secretin administration forms the basis for the standard test used to establish the diagnosis of Zollinger-Ellison syndrome. Cholecystokinin is used in evaluations of gallbladder ejection fraction, a parameter that may have utility in patients who have symptoms of biliary colic but are not found to have gallstones. Of the peptides listed in Table 28-2, glucagon-like peptide-2 (GLP-2) has been identified as a specific and potent intestinotrophic hormone and is currently under clinical evaluation as an intestinotrophic agent in patients suffering from the short bowel syndrome, as discussed in the later Short Bowel Syndrome section.

**Intestinal Adaptation**

The small intestine has the capacity to adapt in response to varying demands imposed by physiologic and pathologic conditions. Of particular relevance to many of the diseases discussed in this chapter is the adaptation that occurs in the remnant intestine following surgical resection of a large portion of the small intestine (massive small bowel resection). Postresection intestinal adaptation has been studied extensively using animal models. Within a few hours after bowel resection, the remnant small intestine displays evidence of epithelial cellular hyperplasia. With additional time, villi lengthen, intestinal absorptive surface area increases, and digestive and absorptive functions improve. Postresection intestinal adaptation in human patients is less well studied, but seems to follow similar steps as those seen in experimental models, and takes 1 to 2 years to complete.

The mechanisms responsible for inducing postresection intestinal adaptation are under active investigation.

*This table indicates which enteroendocrine cell types located in the intestinal epithelium produce these peptides. These peptides are also widely expressed in nonintestinal tissues.

Several classes of effectors that stimulate intestinal growth include specific nutrients, peptide hormones and growth factors, pancreatic secretions, and some cytokines. Nutritional components with intestinal growth-stimulating effects include fiber, fatty acids, triglycerides, glutamine, polyamines, and lectins.

Postresection adaptation serves to compensate for the function of intestine that has been resected. Jejunal resection is generally better tolerated, as ileum shows better capacity to compensate. However, the magnitude of this response is limited. If enough small intestine is resected, a devastating condition known as the short bowel syndrome results. This condition is discussed in the Short Bowel Syndrome section at the end of this chapter.

**SMALL BOWEL OBSTRUCTION**

**Epidemiology**

Mechanical small bowel obstruction is the most frequently encountered surgical disorder of the small intestine. Although a wide range of etiologies for this condition exists, the obstructing lesion can be conceptualized according to its anatomic relationship to the intestinal wall as:

1. **Intraluminal** (e.g., foreign bodies, gallstones, or meconium)
2. **Intramural** (e.g., tumors, Crohn’s disease–associated inflammatory strictures)
3. **Extrinsic** (e.g., adhesions, hernias, or carcinomatosis)

Intra-abdominal adhesions related to prior abdominal surgery account for up to 75% of cases of small bowel obstruction.

Over 300,000 patients are estimated to undergo surgery to treat adhesion-induced small bowel obstruction in the United States annually. A 20-year trend analysis between 1988 and 2007 has documented no decrease in this rate during this time period, highlighting the ongoing problem with this “old” disease.

Less prevalent etiologies for small bowel obstruction include hernias, malignant bowel obstruction, and Crohn’s disease. The frequency with which obstruction related to these conditions is encountered varies according to the patient population and practice setting. Cancer-related small bowel obstructions are commonly due to extrinsic compression or invasion by advanced malignancies arising in organs other than the small bowel; few are due to primary small bowel tumors. The most commonly encountered etiologies of small bowel obstruction are summarized in Table 28-3. Although congenital abnormalities capable of causing small bowel obstruction usually become evident during childhood, they sometimes elude detection and are diagnosed for the first time in adult patients presenting with abdominal symptoms. For example, intestinal malrotation and mid-gut volvulus should not be forgotten when considering the differential

</table>
diagnosis of adult patients with acute or chronic symptoms of small bowel obstruction, especially those without a history of prior abdominal surgery. A rare etiology of obstruction is the superior mesenteric artery syndrome, characterized by compression of the third portion of the duodenum by the superior mesenteric artery as it crosses over this portion of the duodenum. This condition should be considered in young asthenic individuals who have chronic symptoms suggestive of proximal small bowel obstruction.

Pathophysiology
With onset of obstruction, gas and fluid accumulate within the intestinal lumen proximal to the site of obstruction. The intestinal activity increases in an effort to overcome the obstruction, accounting for the colicky pain and the diarrhea that some experience even in the presence of complete bowel obstruction. Most of the gas that accumulates originates from swallowed air, although some is produced within the intestine. The fluid consists of swallowed liquids and gastrointestinal secretions (obstruction stimulates intestinal epithelial secretions). With ongoing gas and fluid accumulation, the bowel distends and intraluminal and intramural pressures rise. The intestinal motility is eventually reduced with fewer contractions. With obstruction, the luminal flora of the small bowel, which is usually sterile, changes, and a variety of organisms have been cultured from the contents. Translocation of these bacteria to regional lymph nodes has been demonstrated, although the significance of this process is not well understood. If the intramural pressure becomes high enough, intestinal microvascular perfusion is impaired, leading to intestinal ischemia and, ultimately, necrosis. This condition is termed strangulated bowel obstruction.

With partial small bowel obstruction, only a portion of the intestinal lumen is occluded, allowing passage of some gas and fluid. The progression of pathophysiologic events described earlier tends to occur more slowly than with complete small bowel obstruction, and development of strangulation is less likely.

A particularly dangerous form of bowel obstruction is closed-loop obstruction in which a segment of intestine is obstructed both proximally and distally (e.g., with volvulus). In such cases, the accumulating gas and fluid cannot escape either proximally or distally from the obstructed segment, leading to a rapid rise in luminal pressure and a rapid progression to strangulation.

Clinical Presentation
The symptoms of small bowel obstruction are colicky abdominal pain, nausea, vomiting, and obstipation. Vomiting is a more prominent symptom with proximal obstructions than distal. The character of vomitus is important because with bacterial overgrowth, the vomitus is more feculent, suggesting a more established obstruction. Continued passage of flatus and/or stool beyond 6 to 12 hours after onset of symptoms is characteristic of partial rather than complete obstruction. The signs of small bowel obstruction include abdominal distention, which is most pronounced if the site of obstruction is in the distal ileum and may be absent if the site of obstruction is in the proximal small intestine. Bowel sounds may be hyperactive initially, but in late stages of bowel obstruction, minimal bowel sounds may be heard. Laboratory findings reflect intravascular volume depletion and consist of hemoconcentration and electrolyte abnormalities. Mild leukocytosis is common.

Features of strangulated obstruction include abdominal pain often disproportionate to the degree of abdominal findings, suggestive of intestinal ischemia. Patients often have tachycardia, localized abdominal tenderness, fever, marked leukocytosis, and acidosis. Any of these findings should alert the clinician to the possibility of strangulation and need for early surgical intervention.

Diagnosis
The diagnostic evaluation should focus on the following goals: (a) distinguish mechanical obstruction from ileus, (b) determine the etiology of the obstruction, (c) discriminate partial from complete obstruction, and (d) discriminate simple from strangulating obstruction.

Important elements to obtain on history include prior abdominal operations (suggesting the presence of adhesions) and the presence of abdominal disorders (e.g., intra-abdominal cancer or inflammatory bowel disease) that may provide insights into the etiology of obstruction. Upon examination, a meticulous search for hernias (particularly in the inguinal and femoral regions) should be conducted.

The diagnosis of small bowel obstruction is usually confirmed with radiographic examination. The abdominal series consists of (a) a radiograph of the abdomen with the patient in a supine position, (b) a radiograph of the abdomen with the patient in an upright position, and (c) a radiograph of the chest with the patient in an upright position. The finding most specific for small bowel obstruction is the triad of dilated small bowel loops (>3 cm in diameter), air-fluid levels seen on upright films, and a paucity of air in the colon. The sensitivity of abdominal radiographs in the detection of small bowel obstruction ranges 70% to 80%. Specificity is low, because ileus and colonic obstruction can be associated with findings that mimic those observed with small bowel obstruction. False-negative findings on radiographs can result when the site of obstruction is located in the proximal small bowel and when the bowel lumen is filled with fluid but no gas, thereby preventing visualization of air-fluid levels or bowel distention. The latter situation is associated with closed-loop obstruction. Despite these limitations, abdominal radiographs remain an important study in patients with suspected small bowel obstruction because of their widespread availability and low cost (Fig. 28-12).

Computed tomography (CT) scanning is 80% to 90% sensitive and 70% to 90% specific in the detection of small bowel obstruction. The findings of small bowel obstruction include a discrete transition zone with dilation of bowel proximally, decompression of bowel distally, intraluminal contrast that does not pass beyond the transition zone, and a colon containing little gas or fluid (Figs. 28-13 and 28-14). CT scanning may also provide evidence for the presence of closed-loop obstruction and strangulation. Closed-loop obstruction is suggested by the presence of a U-shaped or C-shaped dilated bowel loop associated with a radial distribution of mesenteric vessels converging toward a torsion point. Strangulation is suggested by thickening of the bowel wall, pneumatoses intestinales (air in the bowel wall), portal venous gas, mesenteric haziness, and poor uptake of intravenous contrast into the wall of the affected bowel (Fig. 28-15). CT scanning also offers a global evaluation of the abdomen and may therefore reveal the etiology of obstruction. This feature is important in the acute setting when intestinal obstruction represents only one of many diagnoses in patients presenting with acute abdominal conditions.
The CT scan is usually performed after administration of oral water-soluble contrast or diluted barium. The water-soluble contrast has been shown to have prognostic and therapeutic value too. Several studies and a subsequent meta-analysis have shown that appearance of the contrast in the colon within 24 hours is predictive of nonsurgical resolution of bowel obstruction. Although use of oral contrast did not alter the rate of surgical intervention, it did reduce the overall length of hospital stay in those presenting with small bowel obstruction.

A limitation of CT scanning is its low sensitivity (<50%) in the detection of low-grade or partial small bowel obstruction. A subtle transition zone may be difficult to identify in the axial images obtained during CT scanning. In such cases, contrast examinations of the small bowel, either small bowel series (small bowel follow-through) or enteroclysis, can be helpful. For standard small bowel series, contrast is swallowed or instilled into the stomach through a nasogastric tube. Abdominal radiographs are then taken serially as the contrast travels distally in the intestine. Although barium can be used, water-soluble contrast agents, such as Gastrografin, should be used if the possibility of intestinal perforation exists. These examinations are more labor-intensive and less rapidly performed than...
CT scanning but may offer greater sensitivity in the detection of luminal and mural etiologies of obstruction, such as primary intestinal tumors. For enteroclysis, 200 to 250 mL of barium followed by 1 to 2 L of a solution of methylcellulose in water are instilled into the proximal jejunum via a long nasoenteric catheter. The double-contrast technique used in enteroclysis permits a better assessment of mucosal surface and detection of relatively small lesions, even through overlapping small bowel loops. Enteroclysis is rarely performed in the acute setting but offers greater sensitivity than small bowel series in the detection of lesions that may be causing partial small bowel obstruction. Recently, CT enteroclysis has been used and reported to be superior to plain x-ray small bowel contrast studies.

**Therapy**

Small bowel obstruction is usually associated with a marked depletion of intravascular volume due to decreased oral intake, vomiting, and sequestration of fluid in bowel lumen and wall. Therefore, fluid resuscitation is integral to treatment. Isotonic fluid should be given intravenously, and an indwelling bladder catheter may be placed to monitor urine output. Central venous or pulmonary artery catheter monitoring may be necessary to assist with fluid management in patients with underlying cardiac disease and severe dehydration. Broad-spectrum antibiotics are given by some because of concerns that bacterial translocation may occur in the setting of small bowel obstruction; however, there are no data to support this approach.

The stomach should be continuously evacuated of air and fluid using a nasogastric (NG) tube. Effective gastric decompression decreases nausea, distention, and the risk of vomiting and aspiration. Longer nasoenteric tubes, with tips placed into the jejunum or ileum, were favored in the past but are rarely used today, as they are associated with higher complication rates than NG tubes, with no proven greater efficacy in several studies.

The standard therapy for complete small bowel obstruction has generally been expeditious surgery, with the dictum that “the sun should never rise and set on a complete bowel obstruction.” Recently, however, some have advocated nonoperative approaches in management of these patients, provided closed-loop obstruction is ruled out and there is no evidence of intestinal ischemia. Such patients need to be observed closely and undergo serial exams. The rationale for those favoring early surgical intervention is to minimize the risk for bowel strangulation, which is associated with an increased risk for morbidity and mortality. Clinical signs and currently available laboratory tests and imaging studies do not reliably permit the distinction between patients with simple obstruction and those with strangulated obstruction prior to the onset of irreversible ischemia. Therefore, the goal is to operate before the onset of irreversible ischemia. Others note, however, that a period of observation and nasogastric decompression, provided no tachycardia, tenderness, or an increase in white cell count is noted, are appropriate (see Fig. 28-16 for a proposed management algorithm).

However, conservative therapy, in the form of NG decompression and fluid resuscitation, is commonly recommended in the initial recommendation for:

1. Partial small bowel obstruction
2. Obstruction occurring in the early postoperative period
3. Intestinal obstruction due to Crohn’s disease
4. Carcinomatosis

In partial obstruction, progression to strangulation is unlikely to occur, and an attempt at nonoperative resolution is warranted. Nonoperative management has been documented to be successful in 65% to 81% of patients with partial small bowel obstruction. Of those successfully treated nonoperatively, only 5% to 15% have been reported to have symptoms that were not substantially improved within 48 hours after initiation of therapy. Therefore, most patients with partial small bowel obstruction whose symptoms do not improve within 48 hours after initiation of nonoperative therapy should undergo surgery. In a recent study, using the National Inpatient Sample, this principle was further highlighted. The authors concluded that a 2-day limit of watchful waiting before surgery is not associated with an increase in mortality or postoperative morbidity, although inpatient costs were higher.

Patients undergoing nonoperative therapy should be closely monitored for signs suggestive of peritonitis, the development of which would mandate urgent surgery. As stated before, the administration of hypertonic water-soluble contrast agents, such as Gastrografin used in upper gastrointestinal (GI) and small bowel follow-through examinations, causes a shift of fluid into the intestinal lumen, thereby increasing the pressure gradient across the site of obstruction. This effect may accelerate resolution of partial small bowel obstruction; however, there is less evidence that administration of water-soluble contrast agents increases the probability that an episode of bowel obstruction will be successfully managed nonoperatively.

Obstruction presenting in the early postoperative period has been reported to occur in 0.7% patients undergoing laparotomy. Patients undergoing pelvic surgery, especially colorectal procedures, have the greatest risk for developing early postoperative small bowel obstruction. The presence of obstruction should be considered if symptoms of intestinal obstruction occur after the initial return of bowel function or if bowel function fails to return within the expected 3 to 5 days after abdominal surgery. Plain radiographs may demonstrate dilated loops of small intestine with air-fluid levels but are interpreted as normal.

**Figure 28-15.** Intestinal pneumatosis. This computed tomography scan shows intestinal pneumatosis (arrow). The cause of this radiologic finding was intestinal ischemia. Patient was taken emergently to the operating room and underwent resection of an infarcted segment of small bowel.
or nonspecific in up to a third of patients with early postoperative obstruction. CT scanning or a small bowel series is often required to make the diagnosis. Obstruction that occurs in the early postoperative period is usually partial and only rarely is associated with strangulation. Therefore, a period of extended nonoperative therapy (2–3 weeks) consisting of bowel rest, hydration, and total parental nutrition (TPN) administration is usually warranted. However, if complete obstruction is demonstrated or if signs suggestive of peritonitis are detected, expeditious reoperation should be undertaken without delay.

Crohn’s disease as a cause of small bowel obstruction is discussed in more detail later in the Crohn’s Disease section.

Twenty-five to thirty-three percent of patients with a history of cancer who present with small bowel obstruction have adhesions as the etiology of their obstruction and therefore should not be denied appropriate therapy.20 Even in cases in which the obstruction is related to recurrent malignancy, palliative resection or bypass can be performed. Patients with obvious carcinomatosis pose a difficult challenge, given their limited prognosis. Management must be tailored to an individual patient’s prognosis and desires, and relief of the obstruction may be best achieved by a bypass procedure, avoiding a potentially difficult bowel resection.

The operative procedure performed for small bowel obstruction varies according to the etiology of the obstruction. For example, adhesions are lysed, tumors are resected, and hernias are reduced and repaired. Regardless of the etiology, the affected intestine should be examined, and nonviable bowel resected. Criteria suggesting viability are normal color, peristalsis, and marginal arterial pulsations. Usually, visual inspection alone is adequate in judging viability. In borderline cases, a Doppler probe may be used to check for pulsatile flow to the bowel, and arterial perfusion can be verified by visualizing intravenously administered fluorescein dye in the bowel wall under ultraviolet illumination. However, neither technique has been found to be superior to clinical judgment. In general, if the patient is hemodynamically stable, short lengths of bowel of questionable viability should be resected and primary anastomosis of the remaining intestine performed. However, if the viability of a large proportion of the intestine is in question, a concerted effort to preserve intestinal tissue should be made. In such situations, the bowel of uncertain viability should be left intact and the patient re-explored in 24 to 48 hours in a “second-look” operation. At that time, definitive resection of nonviable bowel is completed.

Successful laparoscopic surgery for bowel obstruction is being reported with greater frequency.22,23 Those who undergo successful laparoscopic procedure have a quicker recovery, less complications, and lower costs. Since distended loops of bowel can interfere with adequate visualization, early cases of proximal small bowel obstruction that are likely due to a single

Figure 28-16. Management algorithm of small bowel obstruction. IVF = intravenous fluid; NG = nasogastric; NPO = nothing by mouth.
adhesive band are best suited for this approach. Presence of bowel distention and multiple adhesions can cause these procedures to be difficult and potentially hazardous. Conversion rate to open surgery is between 17% and 33%.21,23

Outcomes

Prognosis is related to the etiology of obstruction. The majority of patients who are treated conservatively for adhesive small bowel obstruction do not require future readmissions; less than 20% of such patients will have a readmission over the subsequent 5 years with another episode of bowel obstruction.23 The perioperative mortality rate associated with surgery for nonstrangulating small bowel obstruction is less than 5%, with most deaths occurring in elderly patients with significant comorbidities. Mortality rates associated with surgery for strangulating obstruction range from 8% to 25%.

Considering the frequency of small bowel obstruction and the varied degree of clinical severity and presentation, there is often no consistency as to whether the patient is admitted to the medical or surgical service, and further variability in whether and when surgery is consulted. Recent studies have shown that a standard hospital-wide policy can help improve care of patients with bowel obstruction, reducing their time to surgery and shortening their length of hospital stay.24

Prevention

With adhesive small bowel obstruction representing a large therapeutic burden, prevention of postoperative adhesions has become an area of great interest. Good surgical technique, careful handling of tissue, and minimal use and exposure of peritoneum to foreign bodies form the cornerstone of adhesion prevention. These measures alone are often inadequate. In patients undergoing colorectal or pelvic surgery, hospital readmission rates of greater than 30% over the subsequent 10 years have been reported for adhesive small bowel obstruction.25

Use of laparoscopic surgery, when possible, has been strongly promoted. A recent study using the Swedish Inpatient Register has shown that, compared to laparoscopy, open surgery is associated with a four-fold increase in risk of small bowel obstruction within 5 years of the index procedure even after accounting for other risk factors such as age, comorbidity, and previous abdominal surgery.26

In those undergoing open surgery, several strategies for adhesion prevention have been tried; however, the only therapy that has shown some success has been the use of hyaluronan-based agents, such as Seprafilm. The use of this barrier has been clearly shown to reduce the incidence of postoperative bowel adhesions; however, its effect in actually reducing the incidence of small bowel obstruction remains less well defined.27 The use of these products is often left to the discretion of the surgeon and the clinical context. Wrapping of an intestinal anastomosis with the material may be associated with increased leak rates and is generally discouraged.28

ILEUS AND OTHER DISORDERS OF INTESTINAL MOTILITY

Ileus and intestinal pseudo-obstruction designate clinical syndromes caused by impaired intestinal motility and are characterized by symptoms and signs of intestinal obstruction in the absence of a lesion-causing mechanical obstruction. Ileus is a major cause of morbidity in hospitalized patients. Postoperative ileus is the most frequently implicated cause of delayed discharge following abdominal operations; its economic impact has been estimated to be between $750 million and $1 billion annually in the United States.29

Ileus is a temporary motility disorder that is reversed with time as the inciting factor is corrected. In contrast, chronic intestinal pseudo-obstruction comprises a spectrum of specific disorders associated with irreversible intestinal dysmotility.

Pathophysiology

Numerous factors capable of impairing intestinal motility, and thus inciting ileus, have been described (Table 28-4). The most frequently encountered factors are abdominal operations, infection and inflammation, electrolyte abnormalities, and drugs.

Following most abdominal operations or injuries, the motility of the GI tract is temporarily impaired. Among the proposed mechanisms responsible for this dysmotility are surgical stress-induced sympathetic reflexes, inflammatory response mediator release, and anesthetic/analgesic side effects, each of which can inhibit intestinal motility.30 The return of normal motility generally follows a characteristic temporal sequence, with small-intestinal motility returning to normal within the first 24 hours after laparotomy and gastric and colonic motility returning to normal by 48 hours and 3 to 5 days, respectively. Because small bowel motility is returned before colonic and gastric motility, listening for bowel sounds is not a reliable indicator that ileus has fully resolved. Functional evidence of coordinated GI motility in the form of passing flatus or a bowel movement is a more useful indicator. Resolution of ileus may be delayed in the presence of other factors capable of inciting ileus such as the presence of intra-abdominal abscesses or electrolyte abnormalities.

Chronic intestinal pseudo-obstruction can be caused by a large number of specific abnormalities affecting intestinal

smooth muscle, the myenteric plexus, or the extraintestinal nervous system (Table 28-5). Visceral myopathies constitute a group of diseases characterized by degeneration and fibrosis of the intestinal muscularis propria. Visceral neuropathies encompass a variety of degenerative disorders of the myenteric and submucosal plexuses. Both sporadic and familial forms of visceral myopathies and neuropathies exist. Systemic disorders involving the smooth muscle, such as progressive systemic sclerosis and progressive muscular dystrophy, and neurologic diseases, such as Parkinson’s disease, can also be complicated by chronic intestinal pseudo-obstruction. In addition, viral infections, such as those associated with cytomegalovirus and Epstein-Barr virus, can cause intestinal pseudo-obstruction.

**Clinical Presentation**

The clinical presentation of ileus resembles that of small bowel obstruction. Inability to tolerate liquids and solids by mouth, nausea, and lack of flatus or bowel movements are the most common symptoms. Vomiting and abdominal distention may occur. Bowel sounds are characteristically diminished or absent, in contrast to the hyperactive bowel sounds that usually accompany mechanical small bowel obstruction. The clinical manifestations of chronic intestinal pseudo-obstruction include variable degrees of nausea and vomiting and abdominal pain and distention.

**Diagnosis**

Routine postoperative ileus should be expected and requires no diagnostic evaluation. If ileus persists beyond 3 to 5 days postoperatively or occurs in the absence of abdominal surgery, diagnostic evaluation to detect specific underlying factors capable of inciting ileus and to rule out the presence of mechanical obstruction is warranted. Patient medication lists should be reviewed for the presence of drugs, especially opiates, known to be associated with impaired intestinal motility. Measurement of serum electrolytes may demonstrate electrolyte abnormalities commonly associated with ileus. Abdominal radiographs are often obtained, but the distinction between ileus and mechanical obstruction may be difficult based on this test alone. In the postoperative setting, CT scanning is the test of choice because it can demonstrate the presence of an intra-abdominal abscess or other evidence of peritoneal sepsis that may be causing ileus and can exclude the presence of complete mechanical obstruction. Distinction of postoperative ileus from early postoperative obstruction can be difficult but is helpful in developing the appropriate management plan.

The diagnosis of chronic pseudo-obstruction is suggested by clinical features and confirmed by radiographic and manometric studies. Diagnostic laparotomy or laparoscopy with full-thickness biopsy of the small intestine may be required to establish the specific underlying cause.

**Therapy**

The management of ileus consists of limiting oral intake and correcting the underlying inciting factor. If vomiting or abdominal distention is prominent, the stomach should be decompressed using a nasogastric tube. Fluid and electrolytes should be administered intravenously until ileus resolves. If the duration of ileus is prolonged, TPN may be required.

Given the frequency of postoperative ileus and its financial impact, a large number of investigations have been conducted to define strategies to reduce its duration. Although often recommended, the use of early ambulation and routine nasogastric intubation has not been demonstrated to be associated with earlier resolution of postoperative ileus. There is some evidence that early postoperative feeding protocols and are generally well tolerated, reduce postoperative ileus, and can result in a shorter hospital stay. The administration of nonsteroidal anti-inflammatory drugs such as ketorolac and concomitant reductions in opioid dosing have been shown to reduce the duration of ileus in most studies. Similarly, the use of perioperative thoracic epidural anesthesia/analgesia with regimens containing local anesthetics combined with limitation or elimination of systemically administered opioids has been shown to reduce duration of postoperative ileus, although they have not reduced the overall length of hospital stay. Interestingly, recent data have suggested that limiting intra- and postoperative fluid administration can also result in reduction of postoperative ileus and shortened hospital stay.

Table 28-6 summarizes some of the measures used to minimize postoperative ileus.

Most other pharmacologic agents, including prokinetic agents, are associated with efficacy-toxicity profiles that are

too unfavorable to warrant routine use. Recently, administration of alvimopan, a novel peripherally active mu-opioid receptor antagonist with limited oral absorption, has been shown to reduce duration of postoperative ileus, hospital stay, and rate of readmissions in several prospective, randomized, placebo-controlled trials and a subsequent meta-analysis. However, any cost savings associated with the use of this drug outside of a clinical trial have been debated.

Surgical interest in minimizing postoperative ileus has led to exploration of other potential avenues. Experiments in rodents have shown reduced postoperative ileus with enteral administration of lipid-rich nutrition, which is believed to work through a CCK-dependent vagovagal reflex.

Therapy of patients with chronic intestinal pseudo-obstruction focuses on palliation of symptoms as well as fluid, electrolyte, and nutritional management. Surgery should be avoided if at all possible. No standard therapies are curative or delay the natural history of any of the specific disorders causing intestinal pseudo-obstruction. Prokinetic agents, such as metoclopramide and erythromycin, are associated with poor efficacy. Cisapride has been associated with palliation of symptoms; however, because of cardiac toxicity and reported deaths, this agent is restricted to compassionate use in the United States.

Patients with refractory disease may require strict limitation of oral intake and long-term TPN administration. Despite these measures, some patients will continue to have severe abdominal pain or such copious intestinal secretions that vomiting and fluid and electrolyte losses remain substantial. These patients may require a decompressive gastrostomy or an extended small bowel resection to remove abnormal intestine. Small-intestinal transplantation has been applied in these patients with increasing frequency; the ultimate role of this modality remains to be defined.

**CROHN’S DISEASE**

Crohn’s disease is a chronic, idiopathic transmural inflammatory disease with a propensity to affect the distal ileum, although any part of the alimentary tract can be involved. Estimates of the incidence of Crohn’s disease in the United States have ranged from 3.6 to 8.8 per 100,000, with recent studies suggesting a prevalence of about 200 cases per 100,000. A dramatic increase in incidence in the United States was observed to occur from the mid-1950s though the early 1970s. Incidence rates have been stable since the 1980s. Substantial regional variations in incidence have been observed, with the highest incidences reported to exist in northern latitudes. The incidence of Crohn’s disease varies among ethnic groups within the same geographic region. For example, members of Eastern European Ashkenazi Jewish population are at two- to four-fold higher risk of developing Crohn’s disease than members of other populations living in the same location. In countries such as China, the prevalence of Crohn’s disease is estimated at 1.38 cases per 100,000, substantially below that seen in the West, but the rates have been on a rapid increase recently.

Most studies suggest that Crohn’s disease is slightly more prevalent in females than in males. The mean age at which patients are diagnosed with Crohn’s disease falls in the third decade of life, with a second smaller peak in the sixth decade of life, giving it a bimodal distribution. However, the age at diagnosis can range from early childhood through the entire lifespan.

Both genetic and environmental factors appear to influence the risk for developing Crohn’s disease. The relative risk among first-degree relatives of patients with Crohn’s disease is 14 to 15 times higher than that of the general population. Approximately one in five patients with Crohn’s disease will report having at least one affected relative. The concordance rate among monozygotic twins is as high as 67%; however, Crohn’s disease is not associated with simple Mendelian inheritance patterns. Although there is a tendency within families for either ulcerative colitis or Crohn’s disease to be present exclusively, mixed kindreds also occur, suggesting the presence of some shared genetic traits as a basis for both diseases.

Higher socioeconomic status is associated with an increased risk of Crohn’s disease. Most studies have found breastfeeding to be protective against the development of Crohn’s disease. Crohn’s disease is more prevalent among smokers. Furthermore, smoking is associated with the increased risk for both the need for surgery and the risk of relapse after surgery for Crohn’s disease.

**Pathophysiology**

Crohn’s disease is characterized by sustained inflammation. Whether this inflammation represents an appropriate response to a yet unrecognized pathogen or an inappropriate response to a normally innocuous stimulus is unknown. Various hypotheses on the roles of environmental and genetic factors in the pathogenesis of Crohn’s disease have been proposed. Many infectious agents have been suggested to be the causative organism of Crohn’s disease. Candidate organisms have included chlamydia, *Listeria monocytogenes*, *Pseudomonas* species, reovirus, *Mycobacterium paratuberculosis*, and many others. There is no conclusive evidence that any of these organisms is the causative agent. Studies using animal models suggest that in a genetically susceptible host, nonpathogenic, commensal enteric flora are sufficient to induce a chronic inflammatory response resembling that associated with Crohn’s disease. In these models, the sustained intestinal inflammation is the result of either abnormal epithelial barrier function or immune dysregulation. Poor barrier function is hypothesized to permit inappropriate exposure of lamina propria lymphocytes to antigenic stimuli derived from the intestinal lumen. In addition, a variety of defects in immune regulatory mechanisms (e.g., overresponsiveness of mucosal T cells to enteric flora-derived antigens) can lead to defective immune tolerance and sustained inflammation.

Specific genetic defects associated with Crohn’s disease in human patients are beginning to be defined. For example, the presence of a locus on chromosome 16 (the so-called IBD1 locus) has been linked to Crohn’s disease. The IBD1 locus has been identified as the *NOD2* gene. Persons with allelic variants on both chromosomes have a 40-fold higher risk of developing Crohn’s disease than those without variant *NOD2* genes. The relevance of this gene to the pathogenesis of Crohn’s disease is biologically plausible, as the protein product of the *NOD2* gene mediates the innate immune response to microbial pathogens. Other putative IBD loci have been identified on other chromosomes (IBD2 on chromosome 12q and IBD3 on chromosome 6) and are under investigation.

Although the pathologic hallmark of Crohn’s disease is focal, transmural inflammation of the intestine, a spectrum of pathologic lesions can be present. The earliest lesion characteristic of Crohn’s disease is the aphthous ulcer. These superficial ulcers are up to 3 mm in diameter and are surrounded by a halo...
of erythema. In the small intestine, aphthous ulcers typically arise over lymphoid aggregates. Granulomas are highly characteristic of Crohn’s disease and are reported to be present in up to 70% of intestinal specimens obtained during surgical resection. These granulomas are noncaseating and can be found in both areas of active disease and apparently normal intestine, in any layer of the bowel wall, and in mesenteric lymph nodes.

As disease progresses, aphthae coalesce into larger, stellate-shaped ulcers. Linear or serpiginous ulcers may form when multiple ulcers fuse in a direction parallel to the longitudinal axis of the intestine. With transverse coalescence of ulcers, a cobblestoned appearance of the mucosa may arise.

With advanced disease, inflammation can be transmural. Serosal involvement results in adhesion of the inflamed bowel to other loops of bowel or other adjacent organs. Transmural inflammation can also result in fibrosis with stricture formation, intra-abdominal abscesses, fistulas, and, rarely, free perforation. Inflammation in Crohn’s disease can affect discontinuous portions of intestine—so-called “skip lesions” that are separated by intervening normal-appearing intestine.

A feature of Crohn’s disease that is grossly evident and helpful in identifying affected segments of intestine during surgery is the presence of fat wrapping, which represents encroachment of mesenteric fat onto the serosal surface of the bowel (Fig. 28-17). This finding is virtually pathognomonic of Crohn’s disease. The presence of fat wrapping correlates well with the presence of underlying acute and chronic inflammation.

Features that allow for differentiation between Crohn’s disease of the colon and ulcerative colitis include the layers of the bowel wall affected (inflammation in ulcerative colitis is limited to the mucosa and submucosa but may involve the full thickness of the bowel wall in Crohn’s disease) and the longitudinal extent of inflammation (inflammation is continuous and characteristically affects the rectum in ulcerative colitis but may be discontinuous and spare the rectum in Crohn’s disease). In the absence of full expression of features of advanced disease, Crohn’s colitis can sometimes be difficult to distinguish from ulcerative colitis. It is also important to remember that although ulcerative colitis is a disease of the colon, it can be associated with inflammatory changes in the distal ileum (backwash ileitis).

Clinical Presentation

The most common symptoms of Crohn’s disease are abdominal pain, diarrhea, and weight loss. However, the clinical features are highly variable among individual patients and depend on which segment(s) of the GI tract is (are) predominantly affected, the intensity of inflammation, and the presence or absence of specific complications. Patients with Crohn’s disease can be classified by their predominant clinical manifestation as having primarily (a) fibrostenotic disease, (b) fistulizing disease, or (c) aggressive inflammatory disease. There is substantial overlap among these disease patterns in individual patients, however. The onset of symptoms is insidious, and once present, their severity follows a waxing and waning course. Constitutional symptoms, particularly weight loss and fever, or growth retardation in children, may also be prominent and are occasionally the sole presenting features of Crohn’s disease.

The disease affects the small bowel in 80% of cases and the colon alone in 20%. In those with small bowel disease, the majority have ileocolic disease. The small bowel alone is affected in 15% to 30% of patients. Isolated perineal and anorectal disease occurs in 5% to 10% of affected patients. Uncommon sites of involvement include the esophagus, stomach, and duodenum.

An estimated one fourth of all patients with Crohn’s disease will have an extraintestinal manifestation of their disease. One fourth of those affected will have more than one manifestation. Many of these complications are common to both Crohn’s disease and ulcerative colitis, although as a whole, they are more prevalent among patients with Crohn’s disease than those with ulcerative colitis. The most common extraintestinal manifestations are listed in Table 28-7. The clinical severity of some of these manifestations, such as erythema nodosum and peripheral arthritis, is correlated with the severity of intestinal inflammation. The severity of other manifestations, such as pyoderma gangrenosum and ankylosing spondylitis, bear no apparent relationship to the severity of intestinal inflammation.

Diagnosis

The diagnosis is usually established with endoscopic findings in a patient with a compatible clinical history. The diagnosis should be considered in those presenting with acute or chronic abdominal pain, especially when localized to the right lower quadrant, chronic diarrhea, evidence of intestinal inflammation on radiography or endoscopy, the discovery of a bowel stricture or fistula arising from the bowel, and evidence of inflammation or granulomas on intestinal histology. Disorders associated with clinical presentations that resemble those of Crohn’s disease include ulcerative colitis, functional bowel disorders such as irritable bowel syndrome, mesenteric ischemia, collagen vascular diseases, carcinoma and lymphoma, diverticular disease, and infectious enteritides. These infectious enteritides are most frequently diagnosed in immunocompromised patients but can also occur in patients with normal immune function. Acute ileitis caused by Campylobacter and Yersinia species can be difficult to distinguish from that caused by an acute presentation of Crohn’s disease. Typhoid enteritis caused by Salmonella typhosa can lead to overt intestinal bleeding and perforation, most often affecting the terminal ileum. The distal ileum and cecum are the most common sites of intestinal involvement by infection due to Mycobacterium tuberculosis. This condition can result in intestinal inflammation, strictures, and fistula formation, similar to those seen in Crohn’s disease.

Figure 28-17. Crohn’s disease. This intraoperative photograph demonstrates encroachment of mesenteric fat onto the serosal surface of the intestine (“fat wrapping”) that is characteristic of intestinal segments affected by active Crohn’s disease.
Cytomegalovirus (CMV) can cause intestinal ulcers, bleeding, and perforation.

No single symptom, sign, or diagnostic test establishes the diagnosis of Crohn’s disease. Instead, the diagnosis is based on a complete assessment of the clinical presentation with confirmatory findings derived from radiographic, endoscopic, and in most cases pathologic tests. Colonoscopy with intubation of terminal ileum is the main diagnostic tool and can reveal focal ulcerations adjacent to areas of normal-appearing mucosa along with polypoid mucosal changes that give a “cobblestone appearance.” Skip areas of involvement are typical, with segments of normal-appearing bowel interrupted by large areas of obvious disease; this pattern is different from the continuous involvement in ulcerative colitis. Pseudopolyps, as seen in ulcerative colitis, are also often present. Contrast examinations of the small bowel and colon may reveal strictures or networks of ulcers and fissures. CT scanning may reveal intra-abdominal abscesses and is useful in acute presentations to rule out the presence of other intra-abdominal disorders. Esophagogastroduodenoscopy (EGD) is done for disease of the proximal alimentary tract. Because Crohn’s disease often affects the small bowel, which is difficult to image, capsule endoscopy has been increasingly used to make this diagnosis (Fig. 28-18).

Several antibodies have also been identified in patients with inflammatory bowel disease, which may have diagnostic value. The most commonly tested antibodies are antineutrophil cytoplasmic antibody (pANCA) and anti-Saccharomyces cerevisiae antibody (ASCA). ASCA+/pANCA– is associated with a diagnosis of Crohn’s disease, while ASCA–/pANCA+ correlates with ulcerative colitis. Although these antibody tests are commercially available, their widespread use has been hampered by low test sensitivities.

Because of the insidious, and often nonspecific, presentation, the diagnosis of Crohn’s disease is typically made only after symptoms have been present for several years. However, in acute presentations, the diagnosis is sometimes made intraoperatively or during surgical evaluation. The initial manifestation of Crohn’s disease can consist of right lower quadrant abdominal mimicking the presentation of acute appendicitis. In patients with this presentation, Crohn’s disease can be discovered for the first time during laparotomy or laparoscopy performed for presumed appendicitis. In some patients, the initial manifestation of Crohn’s disease is an acute abdomen related to small bowel obstruction, intra-abdominal abscess, or free intestinal perforation. In other patients, perianal abscesses and fistulas requiring surgical therapy may be the first manifestation of Crohn’s disease.

Therapy

Because no curative therapies are available for Crohn’s disease, the goal of treatment is to palliate symptoms rather than to achieve cure. Medical therapy is used to induce and maintain disease remission. Surgery is reserved for specific indications described later. In addition nutritional support in the form of aggressive enteral regimens or, if necessary, parenteral nutrition is used to manage the malnutrition that is common in patients with Crohn’s disease.

Medical Therapy. Pharmacologic agents used to treat Crohn’s disease include antibiotics, aminosalicylates, corticosteroids, and immunomodulators. Antibiotics have an adjunctive role in the treatment of infectious complications associated with Crohn’s disease. They are also used to treat patients with perianal disease, enterocutaneous fistulas, and active colonic disease.

Figure 28-18. Crohn’s disease. This image was captured by a wireless capsule endoscope as it was traveling through the small intestine. It demonstrates a superficial ulceration in the small bowel consistent with Crohn’s disease. (Used with permission from Dr. Anne C. Travis, Division of Gastroenterology, Brigham and Women’s Hospital, Boston, MA.)
Most studies have shown oral 5-aminosalicylic acid (5-ASA) drugs (e.g., mesalamine) to be superior to placebo in inducing disease remission. Their efficacy in the maintenance of remission is less clear. Aminosalicylates are associated with minimal toxicity and are available in a variety of formulations that allow for their delivery to specific regions of the alimentary tract. In Crohn’s disease, sulfasalazine, the parent compound of 5-ASA and widely used in ulcerative colitis, has been shown to be less effective than 5-ASA.

Orally administered glucocorticoids are used to treat patients with mildly to moderately severe disease that does not respond to aminosalicylates. Patients with severe active disease usually require intravenous administration of glucocorticoids. Although glucocorticoids are effective in inducing remission, they are ineffective in preventing relapse, and their adverse effect profile makes long-term use hazardous. Therefore, they should be tapered once remission is achieved. Some patients are unable to undergo glucocorticoid tapering without suffering recurrence of symptoms. Such patients are said to have steroid dependence. In these patients, along with those who do not respond to steroids at all (steroid resistant), use of immune modulators should be considered.

The thiopurine antimetabolites azathioprine and its active metabolite, 6-mercaptopurine, have demonstrated efficacy in inducing remission, in maintaining remission, and in allowing for glucocorticoid tapering in glucocorticoid-dependent patients. A response to these medications is usually observed in 3 to 6 months. There is also some evidence that they decrease the risk of relapse after intestinal resection for Crohn’s disease. These agents are relatively safe but can induce bone marrow suppression and promote infectious complications. For patients who do not respond to the thiopurines, methotrexate is an alternative that is usually given intramuscularly before switching to an oral form after achieving symptomatic control. There is little role for cyclosporine in Crohn’s disease; its efficacy/toxicity profile in this disease is poor.

The successful introduction of infliximab (Remicade), an anti–tumor necrosis factor-α (TNF-α) antibody, heralded the era of biologic therapies for inflammatory bowel disease. Infliximab is a chimeric monoclonal anti-TNFα antibody that has been shown to have efficacy in inducing remission and in promoting closure of enterocutaneous fistulas. It is generally used for patients resistant to standard therapy, in order to help taper steroid dosage. Infliximab is generally well tolerated but should not be used in patients with ongoing septic processes, such as undrained intra-abdominal abscesses. Whereas infliximab is a mouse-human chimeric antibody, the newer drugs in this group include adalimumab (Humira), which is a fully human antibody. Antibodies against other targets in this inflammatory pathway have also been developed and are in various stages of clinical evaluation. Recent studies have shown that these biologic therapies can be used safely after surgery for Crohn’s disease.

In a randomized study of 24 patients, those receiving infliximab starting 4 weeks after ileal resection had improved endoscopic and histologic scores at 1-year follow-up compared to those receiving placebo.40

For patients with perianal disease, antibiotic therapy with metronidazole or ciprofloxacin is the primary step. Two to 4 weeks of therapy is needed before improvements are seen, and often long-term therapy is required to prevent relapse. In cases of relapse, azathioprine can be considered. In patients with fistulas, infliximab and azathioprine are drugs of choice.

**Surgical Therapy.** Fifty to seventy percent of patients with Crohn’s disease will ultimately require at least one surgical intervention for their disease.41,42 Surgery is generally reserved for patients whose disease is unresponsive to aggressive medical therapy or who develop complications of their disease (Table 28-8). Failure of medical management may be the indication for surgery if symptoms persist despite aggressive therapy for several months or if symptoms recur whenever aggressive therapy is tapered. Surgery should be considered if medication-induced complications arise, specifically corticosteroid-related complications, such as cushingoid features, cataracts, glaucoma, systemic hypertension, compression fractures, or aseptic necrosis of the femoral head. Growth retardation constitutes an indication for surgery in 30% of children with Crohn’s disease.

One of the most common indications for surgical intervention is intestinal obstruction. Abscesses and fistulas are frequently encountered during operations performed for intestinal obstruction in these patients, but are rarely the only indication for surgery. Most abscesses are amenable to percutaneous drainage, and fistulas, unless associated with symptoms or metabolic derangements, do not require surgical intervention. Less common complications that require surgical intervention are acute GI hemorrhage, perforations, and development of cancer.

Although most commonly, surgery for Crohn’s disease is planned, an uncommon, but not rare, scenario is the intraoperative discovery of inflammation limited to the terminal ileum during operations performed for presumed appendicitis. This scenario can result from an acute presentation of Crohn’s disease or from acute ileitis caused by bacteria such as *Yersinia* or *Campylobacter*. Both conditions should be treated medically; ileal resection is not generally indicated. However, the appendix, even if normal appearing, should be removed (unless the cecum is inflamed, increasing the potential morbidity of this procedure) in order to eliminate appendicitis from the differential diagnosis of abdominal pain in these patients, particularly those with Crohn’s disease who may be destined to have recurring symptoms.

When the diagnosis of Crohn’s disease is known and surgery planned, thorough examination of the entire intestine should be performed. The presence of active disease is suggested by thickening of the bowel wall, narrowing of the lumen, serosal inflammation and coverage by creeping fat, and thickening of the mesentery. Skip lesions are present in approximately...
20% of cases and should be sought. The length of uninvolved small intestine should be noted.

Segmental intestinal resection of grossly evident disease followed by primary anastomosis is the usual procedure of choice. Microscopic evidence of Crohn’s disease at the resection margins does not compromise a safe anastomosis, and frozen-section analysis of resection margins is unnecessary. In a randomized prospective trial, the effects of achieving 2-cm resection margins beyond grossly evident disease were compared with achieving 12-cm resection margins. There were no evident differences with respect to clinical recurrence rates or anastomotic recurrences. Recurrence rates were similar whether margins were histologically free of or involved with Crohn’s disease. An area of controversy in surgical management of Crohn’s disease has been the ideal anastomatic technique for the bowel after intestinal resection. This issue was addressed in a randomized study of 139 patients undergoing an ileocolic resection for Crohn’s disease, with a mean follow-up of 11.9 months. There were no differences in endoscopic or symptomatic disease recurrence between the groups reconstructed using end-to-end sutured (2-0 PDS) anastomosis vs. those with side-to-side staples anastomosis.

An alternative to segmental resection for obstructing lesions is stricturoplasty (Fig. 28-19). This technique allows for preservation of intestinal surface area and is especially well suited to patients with extensive disease and fibrotic strictures who may have undergone previous resection and are at risk for developing short bowel syndrome. In this technique, the bowel is opened longitudinally to expose the lumen. Any intraluminal ulcerations should be biopsied to rule out the presence of neoplasia. Depending on the length of the stricture, the reconstruction can be fashioned in a manner similar to the Heinecke-Mickulicz pyloroplasty (for strictures <12 cm in length) or the Finney pyloroplasty (for longer strictures as much as 25 cm in length). For longer strictures, variations on the standard stricturoplasty, namely the side-to-side isoperistaltic enterenterostomy, have been advocated and used for strictures with mean lengths of 50 cm. Stricturoplasty sites should be marked with metallic clips to facilitate their identification on radiographs and during subsequent operations. Stricturoplasty is associated with recurrence rates that are no different from those associated with segmental resection. Because the affected bowel is left in situ rather than resected, there is the potential for cancer developing at the stricturoplasty site. However, as data on this complication are limited to anecdotes, this risk remains a theoretical one. Stricturoplasty is contraindicated in patients with intra-abdominal abscesses or intestinal fistulas. The presence of a solitary stricture relatively close to a segment for which resection is planned is a relative contraindication. In general, stricturoplasty is performed in cases where single or multiple strictures are identified in diffusely involved segments of bowel or where previous resections have been performed and maintenance of intestinal length is of great importance.

Intestinal bypass procedures are sometimes required in the presence of intramuscular abscesses or if the diseased bowel is coalesced in the form of a dense inflammatory mass, making its mobilization unsafe. Bypass procedures (gastrojejunostomy) are also used in the presence of duodenal strictures, for which stricturoplasty and segmental resection can be technically difficult.

Since the 1990s, laparoscopic surgical techniques have been applied to patients with Crohn’s disease. The inflammatory changes associated with Crohn’s disease such as thickened and foreshortened mesentery, obliterated tissue planes, and friable tissues with engorged vasculature can make the laparoscopic approach challenging. Randomized studies and a meta-analysis have confirmed that laparoscopic surgery for Crohn’s disease is associated with less postoperative pain, shorter duration of ileus, and a shorter hospital stay. The rates of disease recurrence were similar between the two groups.

**Outcomes**

Overall complication rates following surgery for Crohn’s disease range from 15% to 30%. Wound infections, postoperative intra-abdominal abscesses, and anastomotic leaks account for most of these complications.

Most patients whose disease is resected eventually develop recurrence. If recurrence is defined endoscopically, 70% recur within 1 year of a bowel resection and 85% by 3 years. Clinical recurrence, defined as the return of symptoms confirmed as being due to Crohn’s disease, affects 60% of patients by 5 years and 94% by 15 years after intestinal resection. Reoperation becomes necessary in approximately one third of patients by 5 years after the initial operation, with a median time to reoperation of 7 to 10 years.

**INTESTINAL FISTULAS**

A fistula is defined as an abnormal communication between two epithelialized surfaces. The communication occurs between two parts of the GI tract or adjacent organs in an internal fistula (e.g., enterocolonic fistula or colovesicular fistula). An external
fistula (e.g., enterocutaneous fistula or rectovaginal fistula) involves the skin or another external surface epithelium. Enterocutaneous fistulas that drain less than 200 mL of fluid per day are known as low-output fistulas, whereas those that drain more than 500 mL of fluid per day are known as high-output fistulas.

Over 80% of enterocutaneous fistulas represent iatrogenic complications that occur as the result of enterotomies or intestinal anastomotic dehiscences. Fistulas that arise spontaneously without antecedent iatrogenic injury are usually manifestations of progression of underlying Crohn’s disease or cancer.

Pathophysiology
The manifestations of fistulas depend on which structures are involved. Low-resistance enterenteric fistulas, which allow luminal contents to bypass a significant proportion of the small intestine, may result in clinically significant malabsorption. Enterovesicular fistulas often cause recurrent urinary tract infections. The drainage emanating from enterocutaneous fistulas are irritating to the skin and cause excoriation. The loss of enteric luminal contents, particularly from high-output fistulas originating from the proximal small intestine, results in dehydration, electrolyte abnormalities, and malnutrition.

Fistulas have the potential to close spontaneously. Factors inhibiting spontaneous closure, however, include malnutrition, sepsis, inflammatory bowel disease, cancer, radiation, obstruction of the intestine distal to the origin of the fistula, foreign bodies, high output, short fistulous tract (<2 cm) and epithelialization of the fistula tract (Table 28-9).

Clinical Presentation
Iatrogenic enterocutaneous fistulas usually become clinically evident between the fifth and tenth postoperative days. Fever, leukocytosis, prolonged ileus, abdominal tenderness, and wound infection are the initial signs. The diagnosis becomes obvious when drainage of enteric material through the abdominal wound or through existing drains occurs. These fistulas are often associated with intra-abdominal abscesses.

Diagnosis
CT scanning following the administration of enteral contrast is the most useful initial test. Leakage of contrast material from the intestinal lumen can be observed. Intra-abdominal abscesses should be sought and drained percutaneously. If the anatomy of the fistula is not clear on CT scanning, a small bowel series or enteroclysis examination can be obtained to demonstrate the fistula’s site of origin in the bowel. This study is also useful to rule out the presence of intestinal obstruction distal to the site of origin. Occasionally, contrast injected under pressure through a catheter placed percutaneously into the fistula tract, may offer greater sensitivity in localizing the fistula origin.

Therapy
The treatment of enterocutaneous fistulas should proceed through an orderly sequence of steps.49

1. Stabilization. Fluid and electrolyte resuscitation is begun.
   Nutrition is provided, usually through the parenteral route initially. Sepsis is controlled with antibiotics and drainage of abscesses. The skin is protected from the fistula effluent with ostomy appliances or fistula drains.

2. Investigation. The anatomy of the fistula is defined using the studies described earlier.

3. Decision. The available treatment options are considered, and a timeline for conservative measures is determined.

4. Definitive management. This entails the surgical procedure and requires appropriate preoperative planning and surgical experience.

5. Rehabilitation.

The overall objective is to increase the probability of spontaneous closure. Nutrition and time are the key components of this approach. Most patients will require TPN; however, a trial of oral or enteral nutrition should be attempted in patients with low-output fistulas originating from the distal intestine. The somatostatin analogue octreotide is a useful adjunct, particularly in patients with high-output fistulas; its administration reduces the volume of fistula output, thereby facilitating fluid and electrolyte management. Further, octreotide may accelerate the rate at which fistulas close; however, its administration has not clearly been demonstrated to increase the probability of spontaneous closure.

Timing of Surgical Intervention. Most surgeons would pursue 2 to 3 months of conservative therapy before considering surgical intervention. This approach is based on evidence that 90% of fistulas that are going to close do so within 5 weeks and also that surgical intervention after this time period is associated with better outcomes and lower morbidity.50

If the fistula fails to resolve during this period, surgery may be required during which the fistula tract, together with the segment of intestine from which it originates, should be resected. Simple closure of the opening in the intestine from which the fistula originates is associated with high recurrence rates. Patients with intestinal fistulas typically have extensive and dense intra-abdominal adhesions. As a result, operations performed for nonhealing fistulas can present formidable challenges. Successful applications of alternative therapies to close intestinal fistulas such as the use of biologic sealants have been reported. The indications for their use remain to be defined.

Outcomes
Over 50% of intestinal fistulas close spontaneously. A useful mnemonic designates factors that inhibit spontaneous closure of

| Table 28-9 |

intestinal fistulas: “FRIEND” (Foreign body within the fistula tract, Radiation enteritis, Infection/Inflammation at the fistula origin, Epithelialization of the fistula tract, Neoplasm at the fistula origin, Distal obstruction of the intestine) (Table 28-10).

In a recent 23-year old retrospective review of 153 cases of enterocutaneous fistulas that were treated surgically, the majority of fistulas were found to originate from the small bowel and be iatrogenic in nature, with patients having undergone five or more previous abdominal surgeries. Operative repair was associated with a 30-day mortality of approximately 4% and a 1-year mortality of 15%. Morbidity was over 80%. First attempt at surgical repair was successful in 70% of cases, with an overall closure rate of 84% and some patients requiring up to three attempts at surgical repair. The authors identified closure of the abdominal fascia as an important factor in reducing rates of refistulization and postoperative mortality.

In another similar study, fistula recurrence rates of 30% were again documented and were independently associated with high-output fistulas and the type of surgical treatment: operations not involving resection of the fistula had a much higher rate of recurrence.

SMALL BOWEL NEOPLASMS

Adenomas are the most common benign neoplasm of the small intestine. Other benign tumors include fibromas, lipomas, hemangiomas, lymphangiomas, and neurofibromas. The prevalence of small bowel tumors identified at autopsy is 0.2% to 0.3%, which is significantly higher than the rate of operation for small bowel tumors. This suggests that the majority of small bowel tumors are asymptomatic. These lesions are most frequently encountered in the duodenum as incidental findings during esophagogastroduodenoscopic (EGD) examinations (Fig. 28-20). The reported prevalence of duodenal polyps, as detected during EGD performed for other reasons, ranges from 0.3% to 4.6%.55

Benign neoplasms account for 30% to 50% of small bowel tumors and include adenomas, lipomas, hamartomas, and hemangiomas. Primary small bowel cancers are rare, with an estimated incidence of 5300 cases per year in the United States.54 Among small bowel cancers, adenocarcinomas comprise 35% to 50% of all cases, carcinoid tumors comprise 20% to 40%, and lymphomas comprise approximately 10% to 15%. In a retrospective review of a large U.S. database (Surveillance, Epidemiology, and End Results) between 1992 and 2006, of a total of 10,945 small intestine cancers, 4315 were neuroendocrine in origin, 3412 were carcinomas, 2023 were lymphomas, and 1084 were sarcomas.54 GI stromal tumors (GISTs) are the most common mesenchymal tumors arising in the small intestine and comprise the vast majority of tumors that were formerly classified as leiomyomas, leiomyosarcomas, and smooth muscle tumors of the intestine. The small intestine is frequently affected by metastases from or local invasion by cancers originating at other sites. Melanoma, in particular, is associated with a propensity for metastasis to the small intestine.

Most patients with small-intestinal cancers are in their fifth or sixth decade of life. Reported risk factors for developing small-intestinal cancers include consumption of red meat, ingestion of smoked or cured foods, Crohn’s disease, celiac sprue, hereditary nonpolyposis colorectal cancer (HNPCC), familial adenomatous polyposis (FAP), and Peutz-Jeghers syndrome.

Pathophysiology

The small intestine contains over 90% of the mucosal surface area of the GI tract, but only 1.1% to 2.4% of all GI malignancies. Proposed explanations for the low frequency of small-intestinal neoplasms include (a) dilution of environmental carcinogens in the liquid chyme present in the small-intestinal lumen, (b) rapid transit of chyme, limiting the contact time between carcinogens and the intestinal mucosa, (c) a relatively
low concentration of bacteria in small-intestinal chyme and, therefore, a relatively low concentration of carcinogenic products of bacterial metabolism, (d) mucosal protection by secretory IgA and hydrolases such as benzpyrene hydroxylase that may render carcinogens less active, and (e) efficient epithelial cellular apoptotic mechanisms that serve to eliminate clones harboring genetic mutations.

Recent advances have begun to clarify the molecular pathogenesis of small-intestinal adenocarcinomas and GISTs; there has been less progress with respect to the pathogenesis of the other small-intestinal malignancies (see Table 28-10). Small-intestinal adenocarcinomas are believed to arise from pre-existing adenomas through a sequential accumulation of genetic abnormalities in a model similar to that described for the pathogenesis of colorectal cancer. Adenomas are histologically classified as tubular, villous, and tubulovillous. Tubular adenomas have the least aggressive features and tend to be large, sessile, and located in the second portion of the duodenum. Malignant degeneration has been reported to be present in up to 45% of villous adenomas by the time of diagnosis. Patients with FAP have a nearly 100% cumulative lifetime risk of developing duodenal adenomas that have the potential to undergo malignant transformation. The risk of duodenal cancer in these patients is over 100-fold that in the general population. Indeed, duodenal cancer is the leading cause of cancer-related death among patients with FAP who have undergone colectomy. Patients with Peutz-Jeghers syndrome develop hamartomatous polyps; however, these polyps can contain adenomatous foci that can undergo malignant transformation (Fig. 28-21).

A defining feature of GISTs is their gain-of-function mutation of proto-oncogene KIT, a receptor tyrosine kinase. Pathologic KIT signal transduction is believed to be a central event in GIST pathogenesis. The majority of GISTs have activating mutations in the c-kit protooncogene, which cause KIT to become constitutively activated, presumably leading to persistence of cellular growth or survival signals. Because the interstitial cells of Cajal normally express KIT, these cells have been implicated as the cell of origin for GISTs. KIT expression is assessed by staining the tissues for CD117 antigen, which is part of the KIT receptor, and present in 95% of GISTs.

**Clinical Presentation**

Most small-intestinal neoplasms are asymptomatic until they become large. Partial small bowel obstruction, with associated symptoms of crampy abdominal pain and distention, nausea, and vomiting, is the most common mode of presentation. Obstruction can be the result of either luminal narrowing by the tumor itself or intussusception, with the tumor serving as the lead point. Hemorrhage, usually indolent, is the second most common mode of presentation.

Physical examination may be unrevealing. Up to 25% of patients with small-intestinal malignancies are reported to have a palpable abdominal mass. Findings of intestinal obstruction are reported to be present in 25% of patients. Fecal occult blood test may be positive. Jaundice secondary to biliary obstruction or hepatic metastasis may be present. Cachexia, hepatomegaly, and ascites may be present with advanced disease.

Although the clinical presentation is usually not specific for tumor type, some general comments are appropriate. Adenocarcinomas, as well as adenomas (from which most are believed to arise), are most commonly found in the duodenum, except in patients with Crohn’s disease, in whom most are found in the ileum. Lesions in the periampillary location can cause obstructive jaundice or pancreatitis. Adenocarcinomas located in the duodenum tend to be diagnosed earlier in their progression than those located in the jejunum or ileum, which are rarely diagnosed prior to the onset of locally advanced or metastatic disease.

Carcinoid tumors of the small intestine are also usually diagnosed after the development of metastatic disease. These tumors are associated with a more aggressive behavior than the more common appendiceal carcinoid tumors. Approximately 25% to 50% of patients with carcinoid tumor–derived liver metastases will develop manifestations of the carcinoid syndrome. These manifestations include diarrhea, flushing, hypotension, tachycardia, and fibrosis of the endocardium and valves of the right heart. Candidate tumor-derived mediators of the carcinoid syndrome such as serotonin, bradykinin, and substance P undergo nearly complete metabolism during first passage through the liver. As a result, symptoms of carcinoid syndrome are rare in the absence of liver metastases.

Lymphoma may involve the small intestine primarily or as a manifestation of disseminated systemic disease. Primary small-intestinal lymphomas are most commonly located in the ileum, which contains the highest concentration of lymphoid tissue in the intestine. Although partial small bowel obstruction is the most common mode of presentation, 10% of patients with small-intestinal lymphoma present with bowel perforation.

Sixty to seventy percent of GISTs are located in the stomach. The small intestine is the second most common site, containing 25% to 35% of GISTs. There appears to be no regional variation in the prevalence of GISTs within the small intestine. GISTs have a greater propensity to be associated with overt hemorrhage than the other small-intestinal malignancies (Fig. 28-22).

Metastatic tumors involving the small intestine can induce intestinal obstruction and bleeding.
Diagnosis
Because of the absent or nonspecific symptoms associated with most small-intestinal neoplasms, these lesions are rarely diagnosed preoperatively. Laboratory tests are nonspecific, with the exception of elevated serum 5-hydroxyindole acetic acid (5-HIAA) levels in patients with the carcinoid syndrome. Elevated carcinoembryonic antigen (CEA) levels are associated with small-intestinal adenocarcinomas, but only in the presence of liver metastases.

Contrast radiography of the small intestine may demonstrate benign and malignant lesions. Enteroclysis is reported to have a sensitivity of over 90% in the detection of small bowel tumors and is the test of choice, particularly for tumors located in the distal small bowel. Upper GI with small bowel follow-through examinations have reported sensitivities ranging from only 30% to 44%. CT scanning has low sensitivity for detecting mucosal or intramural lesions but can demonstrate large tumors and is useful in the staging of intestinal malignancies. Tumors associated with significant bleeding can be localized with angiography or radioisotope-tagged red blood cell (RBC) scans.

Tumors located in the duodenum can be visualized and biopsied on EGD. In addition, endoscopic ultrasonography (EUS) can offer additional information such as the layers of the intestinal wall involved by the lesion. Occasionally, the distal ileum can be successfully visualized during colonoscopy. Intraoperative enteroscopy can be used to directly visualize small-intestinal tumors beyond the reach of standard endoscopic techniques. Recently, capsule endoscopy and double-balloon enteroscopy have been used to evaluate small bowel.

Therapy
Benign neoplasms of the small intestine that are symptomatic should be surgically resected or removed endoscopically, if feasible. Tumors located in the duodenum, including asymptomatic lesions incidentally found during EGD, can pose the greatest therapeutic challenges. These lesions should be biopsied; symptomatic tumors and adenomas, because of their malignant potential, should be removed. In general, duodenal tumors less than 1 cm in diameter are amenable to endoscopic polypectomy. Lesions greater than 2 cm in diameter are technically difficult to remove endoscopically and may need to be removed surgically. Surgical options include transduodenal polypectomy and segmental duodenal resection. Tumors located in the second portion of the duodenum near the ampulla of Vater may require pancreaticoduodenectomy. EUS may offer utility for duodenal tumors ranging in size between 1 and 2 cm in diameter, with those limited to the mucosa being amenable to endoscopic polypectomy. Recent studies have shown that endoscopic resection of biopsy-proven benign duodenal periampullary adenomas leads to equivalent efficacy to surgery but with lower morbidity. Adenomas can recur; therefore, surveillance endoscopy is required after these procedures.

Duodenal adenomas occurring in the setting of FAP require an especially aggressive approach to management. Patients with FAP should undergo screening EGD starting sometime during their second or third decade of life. Adenomas detected should be removed endoscopically, if possible, followed by surveillance endoscopy in 6 months and yearly thereafter, in the absence of recurrence. If surgery is required, pancreaticoduodenectomy is generally necessary because adenomas in patients with FAP tend to be multiple and sessile, with a predilection for the periampullary region. Further, localized resections are complicated by high recurrence rates. Given the potential for recurrences in the duodenal remnant following pylorus-preserving pancreaticoduodenectomy, there is rationale for recommending the application of standard pancreaticoduodenectomy in these patients. However, recurrences have been reported even following this procedure; therefore, continuing surveillance is necessary. For most adenocarcinomas of the duodenum, except those in the third or fourth portion of the duodenum where a local resection could be considered, pancreaticoduodenectomy is required.

The surgical therapy of jejunal and ileal malignancies usually consists of wide local resection of the intestine harboring the lesion. For adenocarcinomas, a wide excision of corresponding mesentery is done to achieve regional lymphadenectomy, as is done for adenocarcinomas of the colon. In the presence of locally advanced or metastatic disease, palliative intestinal resection or bypass is performed. Chemotherapy has no proven efficacy in the adjuvant or palliative treatment of small-intestinal adenocarcinomas.

The goal of surgical therapy for carcinoids is resection of all visible disease. Localized small-intestinal carcinoid tumors should be treated with segmental intestinal resection and regional lymphadenectomy. Nodal metastases are unusual with tumors less than 1 cm in diameter but are present with 75% to 90% of tumors larger than 3 cm in diameter. In approximately 30% of cases, multiple small-intestinal carcinoid tumors are present. Therefore, the entire small intestine should be examined before planning extent of resection. In the presence of metastatic disease, tumor debulking should be conducted as it can be associated with long-term survival and amelioration of symptoms of the carcinoid syndrome. Response rates of 30% to 50% have been reported with chemotherapy regimens based on
agents such as doxorubicin, 5-fluorouracil, and streptozocin. However, none of these regimens is associated with a clearly demonstrable impact on the natural history of disease. Octreotide is the most effective pharmacologic agent for management of symptoms of carcinoid syndrome.

Localized small-intestinal lymphoma should be treated with segmental resection of the involved intestine and adjacent mesentery. If the small intestine is diffusely affected by lymphoma, chemotherapy rather than surgical resection should be the primary therapy. The value to adjuvant chemotherapy after resection of localized lymphoma is controversial.

Small-intestinal GISTs should be treated with segmental intestinal resection. If the diagnosis is known prior to resection, wide lymphadenectomy can be avoided as GISTs are rarely associated with lymph node metastases. GISTs are resistant to conventional chemotherapy agents. Imatinib (Gleevec) is a tyrosine kinase inhibitor with potent activity against the tyrosine kinase KIT and is used in those with metastatic disease. Clinical trials have shown that 80% of patients with unresectable or metastatic GISTs derive clinical benefit from the administration of imatinib, with 50% to 60% having objective evidence of reduction in tumor volume. Imatinib has shown great promise as a neoadjuvant and adjuvant therapy of GISTs. Studies have emphasized the potential for development of tumor resistance to this agent. In this setting, an alternative tyrosine kinas inhibitor, sunitinib, has been used with good results.

Metastatic cancers affecting the small intestine that are symptomatic should be treated with palliative resection or bypass except in the most advanced cases. Systemic therapy may be offered if effective chemotherapy exists for the primary cancer.

Outcomes
Complete resection of duodenal adenocarcinomas is associated with postoperative 5-year survival rates ranging from 50% to 60%. Complete resection of adenocarcinomas located in the jejunum or ileum is associated with 5-year survival rates of 20% to 30%. Five-year survival rates of 75% to 95% following resection of localized small-intestinal carcinoid tumors have been reported. In the presence of carcinoid tumor–derived liver metastases, 5-year survival rates of 19% to 54% have been reported. The overall 5-year survival rate for patients diagnosed with intestinal lymphoma ranges from 20% to 40%. For patients with localized lymphoma amenable to surgical resection, the 5-year survival rate is 60%.

The recurrence rate after resection of GISTs averages 35%. The 5-year survival rate after surgical resection has been reported to range from 35% to 60%. Both tumor size and mitotic index are independently correlated with prognosis. Low-grade tumors (mitotic index <10 per high-power field) measuring less than 5 cm in diameter are associated with excellent prognosis.

RADIATION ENTERITIS

Radiation therapy is a component of multimodality therapy for many intra-abdominal and pelvic cancers such as those of the cervix, endometrium, ovary, bladder, prostate, and rectum. An undesired side effect of radiation therapy is radiation-induced injury to the small intestine, which can present clinically as two distinct syndromes: acute and chronic radiation enteritis.

Acute radiation enteritis is a transient condition that occurs in approximately 75% of patients undergoing radiation therapy for abdominal and pelvic cancers. Chronic radiation is enteritis is inexorable and develops in approximately 5% to 15% of these patients.

Pathophysiology
Radiation induces cellular injury directly and through the generation of free radicals. The principal mechanism of radiation-induced cell death is believed to be apoptosis resulting from free radical–induced breaks in double-stranded DNA. Because radiation has its greatest impact on rapidly proliferating cells, the small-intestinal epithelium is acutely susceptible to radiation-induced injury. Pathologic correlates of this acute injury include villus blunting and a dense infiltrate of leukocytes and plasma cells within the crypts. With severe cases, mucosal sloughing, ulceration, and hemorrhage are observed. The intensity of injury is related to the dose of radiation administered, with most cases occurring in patients who have received at least 4500 cGy. Risk factors for acute radiation enteritis include conditions that may limit splanchnic perfusion such as hypertension, diabetes mellitus, coronary artery disease, and restricted mobility of the small intestine due to adhesions. Injury is potentiated by concomitant administration of chemotherapeutic agents such as doxorubicin, 5-fluorouracil, dacitoximycin, and methotrexate that act as radiation sensitizers. Because of the intestinal epithelium’s capacity for regeneration, the mucosal injury that is characteristic of acute radiation enteritis resolves after the cessation of radiation therapy.

In contrast, chronic radiation enteritis is characterized by a progressive occlusive vasculitis that leads to chronic ischemia and fibrosis that affects all layers of the intestinal wall, rather than the mucosa alone. These changes can lead to strictures, abscesses, and fistulas, which are responsible for the clinical manifestations of chronic radiation enteritis.

Clinical Presentation
The most common manifestations of acute radiation enteritis are nausea, vomiting, diarrhea, and crampy abdominal pain. Symptoms are generally transient and subside after the discontinuation of radiation therapy. Because the diagnosis is usually obvious, given the clinical context, no specific diagnostic tests are required. However, if patients develop signs suggestive of peritonitis, CT scanning should be performed to rule out the presence of other conditions capable of causing acute abdominal syndromes.

The clinical manifestations of chronic radiation enteritis usually become evident within 2 years of radiation administration, although they can begin as early as several months or as late as decades afterward. The most common clinical presentation is one of partial small bowel obstruction, with nausea, vomiting, intermittent abdominal distention, crampy abdominal pain, and weight loss being the most common symptoms. The terminal ileum is the most frequently affected segment. Other manifestations of chronic radiation enteritis include complete bowel obstruction, acute or chronic intestinal hemorrhage, and abscess or fistula formation.

Diagnosis
Evaluation of patients suspected of having chronic radiation enteritis should include review of the records of their radiation treatments for information on total radiation dose administered, fractionation, and volume of treatment. Areas that received high doses should be noted, as lesions subsequently found in imaging studies usually localize to areas that had received high.
radiation doses. Enteroclysis is the most accurate imaging test for diagnosing chronic radiation enteritis, with reported sensitivities and specificities of over 90% (Fig. 28-23). CT scan findings are neither very sensitive nor specific for chronic radiation enteritis. However, CT scanning should be obtained to rule out the presence of recurrent cancer since its clinical manifestations may overlap with those of chronic radiation enteritis.

**Therapy**

Most cases of acute radiation enteritis are self-limited. Supportive therapy, including the administration of antiemetics, is usually sufficient. Patients with diarrhea-induced dehydration may require hospital admission and parenteral fluid administration. Rarely are symptoms severe enough to necessitate reduction in or cessation of radiation therapy.

In contrast, the treatment of chronic radiation enteritis represents a formidable challenge. Surgery for this condition is difficult, is associated with high morbidity rates, and should be avoided in the absence of specific indications such as high-grade obstruction, perforation, hemorrhage, intra-abdominal abscesses, and fistulas. The goal of surgery is limited resection of diseased intestine with primary anastomosis between healthy bowel segments. However, the characteristically diffuse nature of fibrosis and dense adhesions among bowel segments can make limited resection difficult to achieve. Further, it is difficult to distinguish between normal and irradiated intestine intraoperatively by either gross inspection or even frozen section analysis. This distinction is important as anastomoses between irradiated segments of intestine have been associated with leak rates as high as 50%. If limited resection is not achievable, an intestinal bypass procedure may be an option, except in cases for which hemorrhage is the surgical indication. There remain cases in which resections extensive enough to cause short bowel syndrome are unavoidable. This condition is discussed in detail later in the Short Bowel Syndrome section.

**Outcomes**

Acute radiation injury to the intestine is self-limited; its severity is not correlated with the probability of chronic radiation enteritis developing. Surgery for chronic radiation enteritis is associated with high morbidity rates and reported mortality rates averaging 10%.

**Prevention**

In view of significant morbidity associated with radiation enteritis, groups have studied possible measures to reduce or prevent such side effects. Keeping radiation exposure to below 5000 cGy is associated with minimal long-term side effects and recommended where clinically possible.

Multi-beam radiation techniques to minimize the area of maximal radiation exposure and tilt tables to move the bowel out of the pelvis during radiation are increasingly used. Few small studies have suggested that oral sulfasalazine may help reduce the incidence of acute radiation-induced enteritis.

In patients undergoing pelvic surgery who are likely to require postoperative radiation therapy, surgical techniques that keep the small bowel out of the pelvis have been recommended. These measures include use of absorbable mesh sling to separate the pelvis from the true abdominal cavity and prevent the small bowel from being exposed to pelvic radiation.

**MECKEL’S DIVERTICULUM**

Meckel’s diverticulum is the most prevalent congenital anomaly of the GI tract, affecting approximately 2% of the general population. Meckel’s diverticula are designated true diverticula because their walls contain all of the layers found in normal small intestine. Their location varies among individual patients, but they are usually found in the ileum within 100 cm of the ileocecal valve (Fig. 28-24). Approximately 60% of Meckel’s diverticula contain heterotopic mucosa, of which over 60% consist of...
gastric mucosa. Pancreatic acini are the next most common; others include Brunner’s glands, pancreatic islets, colonic mucosa, endometriosis, and hepatobiliary tissues. A useful, although crude, mnemonic describing Meckel’s diverticulum is the “rule of two’s”: 2% prevalence, 2:1 male predominance, location 2 feet proximal to the ileocecal valve in adults, and half of those who are symptomatic are under 2 years of age.

Pathophysiology
During the eighth week of gestation, the omphalomesenteric (vitelline) duct normally undergoes obliteration. Failure or incomplete vitelline duct obliteration results in a spectrum of abnormalities, the most common of which is Meckel’s diverticulum. Other abnormalities include omphalomesenteric fistula, enterocyst, and a fibrous band connecting the intestine to the umbilicus. A remnant of the left vitelline artery can persist to form a mesodiverticular band tethering a Meckel’s diverticulum to the ileal mesentery.

Bleeding associated with Meckel’s diverticulum is usually the result of ileal mucosal ulceration that occurs adjacent to acid-producing, heterotopic gastric mucosa located within the diverticulum. Intestinal obstruction associated with Meckel’s diverticulum can result from several mechanisms:
1. Volvulus of the intestine around the fibrous band attaching the diverticulum to the umbilicus
2. Entrapment of intestine by a mesodiverticular band (Fig. 28-25)
3. Intussusception with the diverticulum acting as a lead point
4. Stricture secondary to chronic diverticulitis

Meckel’s diverticulum can be found in inguinal or femoral hernia sacs (known as Littre’s hernia). These hernias, when incarcerated, can cause intestinal obstruction.

Clinical Presentation
Meckel’s diverticula are asymptomatic unless associated complications arise. The lifetime incidence rate of complications arising in patients with Meckel’s diverticula has been estimated to be approximately 4% to 6%. Although initial data had suggested that the risk of developing a complication related to Meckel’s diverticulum decreases with age, this has been now been questioned. In a population-based review at Olmsted County, MN, Cullen and colleagues showed that the risk of developing Meckel’s-related complications does not change with age.

The most common presentations associated with symptomatic Meckel’s diverticulum are bleeding, intestinal obstruction, and diverticulitis. Bleeding is the most common presentation in children with Meckel’s diverticula, representing over 50% of Meckel’s diverticulum–related complications among patients less than 18 years of age. Bleeding associated with Meckel’s diverticulum is rare among patients older than 30 years of age.

Intestinal obstruction is the most common presentation in adults with Meckel’s diverticula. Diverticulitis, present in 20% of patients with symptomatic Meckel’s diverticula, is associated with a clinical syndrome that is indistinguishable from acute appendicitis. Neoplasms, most commonly carcinoid tumors, are present in 0.5% to 3.2% of symptomatic Meckel’s diverticula that are resected.

Diagnosis
Most Meckel’s diverticula are discovered incidentally on radiographic imaging, during endoscopy, or at the time of surgery. In the absence of bleeding, Meckel’s diverticula rarely are diagnosed prior to the time of surgical intervention. For those presenting with symptoms suggestive of a Meckel’s diverticulum, confirmatory imaging can be challenging. The sensitivity of CT scanning for the detection of Meckel’s diverticula is too low to be clinically useful. Enteroclysis is associated with an accuracy of 75% but is usually not applicable during acute presentations of complications related to Meckel’s diverticula. Radionuclide scans (⁹⁹ᵐTc-pertechnetate) can be helpful in the diagnosis of Meckel’s diverticulum; however, this test is positive only when the diverticulum contains associated ectopic gastric mucosa that is capable of uptake of the tracer (Fig. 28-26). The accuracy of radionuclide scanning is reported to be 90% in pediatric patients but less than 50% in adults. Angiography can localize the site of bleeding during acute hemorrhage related to Meckel’s diverticula.

Therapy
The surgical treatment of symptomatic Meckel’s diverticulum should consist of diverticulectomy with removal of associated bands connecting the diverticulum to the abdominal wall or intestinal mesentery. If the indication for diverticulectomy is bleeding, segmental resection of ileum that includes both the diverticulum and the adjacent ileal peptic ulcer should be performed. Segmental ileal resection may also be necessary if the diverticulum contains a tumor or if the base of the diverticulum is inflamed or perforated.

The surgical treatment of symptomatic Meckel’s diverticulum should consist of diverticulectomy with removal of associated bands connecting the diverticulum to the abdominal wall or intestinal mesentery. If the indication for diverticulectomy is bleeding, segmental resection of ileum that includes both the diverticulum and the adjacent ileal peptic ulcer should be performed. Segmental ileal resection may also be necessary if the diverticulum contains a tumor or if the base of the diverticulum is inflamed or perforated.

Figure 28-25. A, Meckel’s diverticulum with mesodiverticular band. B, One mechanism by which Meckel’s diverticulum can cause small bowel obstruction is entrapment of the intestine by a mesodiverticular band.
The management of incidentally found (asymptomatic) Meckel’s diverticula is controversial. Until recently, most authors recommended against prophylactic removal of asymptomatic Meckel’s diverticula, given the low lifetime incidence of complications. More recently, greater enthusiasm for prophylactic diverticulectomy has appeared in the literature. Proponents of this approach cite the minimal morbidity associated with removing Meckel’s diverticula and the possibility that previous estimates of the lifetime incidence of complications related to Meckel’s diverticula may be erroneously low. Other authors have advocated a selective approach, with a recommendation to remove diverticula attached by bands and those with narrow bases, on the assumption that these diverticula are more likely to develop complications. No controlled data supporting or refuting these recommendations exist.

**ACQUIRED DIVERTICULA**

Acquired diverticula are designated *false diverticula* because their walls consist of mucosa and submucosa but lack a complete muscularis. Acquired diverticula are more common in the duodenum and tend to be located near the ampulla; such diverticula are known as *periampullary*, *juxtapapillary*, or *perivaterian diverticula*. Approximately 75% of juxtapapillary diverticula arise on the medial wall of the duodenum. Acquired diverticula in the jejunum or ileum are known as *jejunoileal diverticula*. Eighty percent of jejunoileal diverticula are localized to the jejunum, 15% to the ileum, and 5% to both jejunum and ileum. Diverticula in the jejunum tend to be large and accompanied by multiple other diverticula, whereas those in the ileum tend to be small and solitary.

The prevalence of duodenal diverticula, as detected on upper GI examinations (Fig. 28-27), has been reported to range from 0.16% to 6%. Their prevalence, as detected during endoscopic retrograde cholangiography (ERCP) examinations, has been reported to range from 5% to 27%. A 23% prevalence rate has been reported in an autopsy series. The prevalence of duodenal diverticula increases with age; they are rare in patients under the age of 40 years. The mean age of diagnosis ranges from 56 to 76 years.

The prevalence of jejunoileal diverticula (Fig. 28-28) has been estimated to range from 1% to 5%. Their prevalence increases with age; most patients diagnosed with these diverticula are in the sixth and seventh decades of life.

**Pathophysiology**

The pathogenesis of acquired diverticula is hypothesized to be related to acquired abnormalities of intestinal smooth muscle or dysregulated motility, leading to herniation of mucosa and submucosa through weakened areas of muscularis.

*Figure 28-26.* Meckel’s diverticulum with ectopic gastric tissue. The diagnosis was made in this patient using 99mTc-pertechnetate scintigraphy. The study revealed an abnormal focus of radiotracer accumulation in the right lower quadrant (arrow).
Acquired diverticula can be associated with bacterial overgrowth, leading to vitamin B₁₂ deficiency, megaloblastic anemia, malabsorption, and steatorrhea. Periampullary duodenal diverticula have been described to become distended with intraluminal debris and to compress the common bile duct or pancreatic duct, thus causing obstructive jaundice or pancreatitis, respectively. Jejunoileal diverticula can also cause intestinal obstruction through intussusception or compression of adjacent bowel.

Clinical Presentation
Acquired diverticula are asymptomatic unless associated complications arise. Such complications are estimated to occur in 6% to 10% of patients with acquired diverticula and include intestinal obstruction, diverticulitis, hemorrhage, perforation, and malabsorption. Periampullary duodenal diverticula may be associated with choledocholithiasis, cholangitis, recurrent pancreatitis, and sphincter of Oddi dysfunction. However, a clear link between the presence of the diverticula and the development of these
conditions has not been demonstrated. Symptoms such as intermittent abdominal pain, flatulence, diarrhea, and constipation are reported to be present in 10% to 30% of patients with jejunoileal diverticula. The relationship between these symptoms and the presence of diverticula is similarly unclear.

**Diagnosis**

Most acquired diverticula are discovered incidentally on radiographic imaging, during endoscopy, or at the time of surgery. On ultrasound and CT scanning, duodenal diverticula may be mistaken for pancreatic pseudocysts and fluid collections, biliary cysts, and periampullary neoplasms. These lesions can be missed on endoscopy, particularly with forward-viewing endoscopes, and are best diagnosed on upper GI radiographs. Enteroclysis is the most sensitive test for detecting jejunoileal diverticula.

**Therapy**

Asymptomatic acquired diverticula should be left alone. Bacterial overgrowth associated with acquired diverticula is treated with antibiotics. Other complications, such as bleeding and diverticulitis, are treated with segmental intestinal resection for diverticula located in the jejunum or ileum.

Bleeding and obstruction related to lateral duodenal diverticula are generally treated with diverticulectomy alone. These procedures can be technically difficult for medial duodenal diverticula that penetrate into the substance of the pancreas. Complications related to these medial duodenal diverticula should be managed nonoperatively, if possible, using endoscopy. In emergent situations, bleeding related to medial duodenal diverticula can be controlled using a lateral duodenotomy and oversewing of the bleeding vessel. Similarly, perforation can be managed with wide drainage rather than complex surgery. Whether diverticulectomy should be done in patients with biliary or pancreatic symptoms is controversial and is not routinely recommended.  

**MESENTERIC ISCHEMIA**

Mesenteric ischemia can present as one of two distinct clinical syndromes: acute mesenteric ischemia and chronic mesenteric ischemia.

Four distinct pathophysiologic mechanisms can lead to acute mesenteric ischemia:

1. Arterial embolus
2. Arterial thrombosis
3. Vasospasm (also known as nonocclusive mesenteric ischemia [NOMI])
4. Venous thrombosis

Emboli is the most common cause of acute mesenteric ischemia and is responsible for over 50% of cases. The embolic source is usually in the heart, most often the left atrial or venricular thrombi or valvular lesions. Indeed, up to 95% of patients with acute mesenteric ischemia due to emboli will have a documented history of cardiac disease. Embolism to the superior mesenteric artery accounts for 50% of cases; most of these emboli become wedged and cause occlusion at branch points in the mid to distal superior mesenteric artery, usually distal to the origin of the middle colic artery. In contrast, acute occlusions due to thrombosis tend to occur in the proximal mesenteric arteries, near their origins. Acute thrombosis is usually superimposed on pre-existing atherosclerotic lesions at these sites. NOMI is the result of vasospasm and is usually diagnosed in critically ill patients receiving vasopressor agents. Mesenteric venous thrombosis accounts for 5% to 15% of cases of acute mesenteric ischemia and involves the superior mesenteric vein in 95% of cases. The inferior mesenteric vein is only rarely involved. Mesenteric venous thrombosis is classified as primary if no etiologic factor is identifiable or as secondary if an etiologic factor, such as heritable or acquired coagulation disorders, is identified.

Regardless of the pathophysiologic mechanism, acute mesenteric ischemia can lead to intestinal mucosal sloughing within 3 hours of onset and full-thickness intestinal infarction by 6 hours.

In contrast, chronic mesenteric ischemia develops insidiously, allowing for development of collateral circulation, and, therefore, rarely leads to intestinal infarction. Chronic mesenteric ischemia results from atherosclerotic lesions in the main splanchnic arteries (celiac, superior mesenteric, and inferior mesenteric arteries). In most patients with symptoms attributable to chronic mesenteric ischemia, at least two of these arteries are either occluded or severely stenosed. A chronic form of mesenteric venous thrombosis can involve the portal or splenic veins and may lead to portal hypertension, with resulting esophageal varices, splenomegaly, and hypersplenism.

Severe abdominal pain, out of proportion to the degree of tenderness on examination, is the hallmark of acute mesenteric ischemia, regardless of the pathophysiologic mechanism. The pain is typically perceived to be colicky and most severe in the mid-abdomen. Associated symptoms can include nausea, vomiting, and diarrhea. Physical findings are characteristically absent early in the course of ischemia. With the onset of bowel infarction, abdominal distension, peritonitis, and passage of bloody stools occur.

Chronic mesenteric ischemia presents insidiously. Postprandial abdominal pain is the most prevalent symptom, producing a characteristic aversion to food (“food fear”) and weight loss. These patients are often thought to have a malignancy and suffer a prolonged period of symptoms before the correct diagnosis is made.

Most patients with chronic mesenteric venous thrombosis are asymptomatic because of the presence of extensive collateral venous drainage routes; this condition is usually discovered as an incidental finding on imaging studies. However, some patients with chronic mesenteric venous thrombosis present with bleeding from esophagogastric varices.

The diagnosis and management of these disorders, which are of primary vascular origin, are discussed in the section on mesenteric artery occlusive disease in the chapter on arterial disease.

**MISCELLANEOUS CONDITIONS**

**Obscure Gastrointestinal Bleeding**

Up to 90% of lesions responsible for GI bleeding are within the reach EGD and colonoscopy. Obscure GI bleeding refers to GI bleeding for which no source has been identified by routine endoscopic studies (EGD and colonoscopy). Overt GI bleeding refers to the presence of hematemesis, melena, or hematochezia. In contrast, occult GI bleeding occurs in the absence of overt bleeding and is identified on laboratory tests (e.g., iron-deficiency anemia) or examination of the stool (e.g., positive guaiac test). Obscure GI bleeding is occult in 20% of cases.
Obscure bleeding can be frustrating for both the patient and the clinician, and this is particularly true for obscure-overt bleeding, which cannot be localized despite aggressive diagnostic measures. One study from a tertiary referral center reported that the typical patient with obscure-overt bleeding had suffered intermittent episodes of hemorrhage for 26 months, had undergone up to 20 diagnostic tests, and had received an average of 20 units of blood before reaching a diagnosis. Most of the small bowel is beyond the reach of these examinations and, hence, contains most lesions responsible for obscure GI bleeding. Small-intestinal angiodysplasias account for approximately 75% of cases in adults, and neoplasms account for approximately 10%. Meckel’s diverticulum is the most common etiology of obscure GI bleeding in children. Other etiologies of obscure GI bleeding include Crohn’s disease, infectious enteritides, nonsteroidal anti-inflammatory drug (NSAID)-induced ulcers and erosions, vasculitis, ischemia, varices, diverticula, and intussusception.

The diagnostic evaluation of patients with obscure GI bleeding should be tailored to the severity of bleeding and to the availability of technology and expertise. Enteroscopy is playing an increasingly important role. Several endoscopic techniques for visualizing the small intestine are available: push enteroscopy, Sonde enteroscopy, intraoperative enteroscopy, double-balloon endoscopy, and wireless capsule enteroscopy.

Push enteroscopy entails advancing a long endoscope (such as a pediatric or adult colonoscope or a specialized instrument) beyond the ligament of Treitz into the proximal jejunum. This procedure can allow for visualization of approximately 60 cm of the proximal jejunum. Diagnostic yield in patients with obscure GI bleeding ranges from 3% to 65%. In addition to diagnosis, push enteroscopy allows for cautery and endoscopic ligation for patients with endoscopically controllable bleeding.

In Sonde enteroscopy, a long, thin fiberoptic instrument is propelled through the intestine by peristalsis following inflation of a balloon at the instrument’s tip. Visualization is done during instrument withdrawal; approximately 50% to 75% of the small-intestinal mucosa can be examined. However, this instrument lacks biopsy or therapeutic capability. Further, it lacks tip deflection capability, limiting complete mucosal visualization, and has therefore been abandoned in favor of capsule endoscopy.

Wireless capsule enteroscopy relies on a radiotelemetry capsule enteroscope that is small enough to swallow and has no external wires, fiberoptic bundles, or cables. While the capsule is being propelled through the intestine by peristalsis, video images are transmitted using radiotelemetry to an array of detectors attached to the patient’s body. These detectors capture the images and permit continuous triangulation of the capsule location in the abdomen, facilitating the localization of lesions detected. The entire system is portable, allowing the patient to be ambulatory during the entire examination. Capsule endoscopy is an excellent tool in the patient who is hemodynamically stable but continues to bleed. This technique has reported success rates as high as 90% in identifying a small bowel pathology. Although many studies have shown an improved diagnostic yield for small bowel lesions with capsule endoscopy, the impact of this new imaging modality on actual patient outcomes was not studied until recently. In a randomized study of patients with obscure GI bleeding, evaluation with capsule endoscopy vs. small bowel contrast study had a much higher diagnostic yield (30% vs. 7%, respectively); however, this did not translate into an improvement in outcomes. The rates of rebleeding, hospitalization, need for blood transfusion, and therapeutic interventions were similar between the two arms.

The inability to perform biopsies or carry out any therapeutic interventions of capsule endoscope likely prevents the improved diagnostic yield of the test from translating into improved patient outcomes and highlights the continuing challenge with evaluation of the small bowel.

For patients in whom bleeding from an obscure GI source has apparently stopped, push enteroscopy or capsule enteroscopy is a reasonable initial study. If these examinations do not reveal a potential source of bleeding, then enteroclysis should be performed. Standard small bowel follow-through examinations are associated with a low diagnostic yield and should be avoided. If still no diagnosis has been made, a “watch-and-wait” approach is reasonable, although angiography should be considered if the prior episode of bleeding was overt. Angiography can reveal angiodysplasia and vascular tumors in the small intestine even in the absence of ongoing bleeding.

For persistent mild bleeding from an obscure GI source, push and capsule enteroscopy can be used. If these examinations are nondiagnostic, then 99m Tc-labeled RBC scanning should be performed and, if positive, followed by angiography to localize the source of bleeding. 99m Tc-pertechnetate scintigraphy to diagnose Meckel’s diverticulum should be considered, although its yield in patients older than 40 years of age is extremely low. Patients who remain undiagnosed but continue to bleed and those with recurrent episodic bleeding significant enough to require blood transfusions should then undergo exploration with intraoperative enteroscopy.

For patients with persistent severe bleeding from an obscure source should undergo angiography to help localize the bleeding source. Therapy can be tailored based on the source. Push enteroscopy can also be attempted, but capsule enteroscopy is too slow to be applicable in this setting. If these examinations fail to localize the source of bleeding, exploratory laparoscopy or laparotomy with intraoperative enteroscopy is indicated. Intraoperative enteroscopy can be done during either laparotomy or laparoscopy. An endoscope (usually a colonoscope) is inserted into the small bowel through peroral intubation or through an enterotomy made in the small bowel or cecum. The endoscope is advanced by successively telescoping short segments of intestine onto the end to the instrument. In addition to the endoscopic image, the transilluminated bowel should be examined externally with the operating room lights dimmed, as this maneuver may facilitate the identification of angiodysplasias. Identified lesions should be marked with a suture placed on the serosal surface of the bowel; these lesions can be resected after completion of endoscopy. Examination should be performed during instrument insertion rather than withdrawal because instrument-induced mucosal trauma can be confused with angiodysplasias.

Fig. 28-29 provides a diagnostic and management algorithm for patients with obscure GI bleeding.

Small Bowel Perforation

Prior to the 1980s, duodenal perforation due to peptic ulcer disease was the most common form of small bowel perforation. Today, iatrogenic injury incurred during GI endoscopy is the most common cause of small bowel perforation. Other etiologies of small bowel perforation include infections (especially tuberculosis, typhoid, and CMV), Crohn’s disease, ischemia, drugs (e.g., potassium- and NSAID-induced ulcers), radiation-induced
injury, Meckel’s and acquired diverticula, neoplasms (especially lymphoma, adenocarcinoma, and melanoma), and foreign bodies.

Among iatrogenic injuries, duodenal perforation during ERCP with endoscopic sphincterotomy (ES) is the most common. This complication occurs in 0.3% to 2.1% of cases. Patients who have undergone Billroth II gastrectomy are at increased risk of duodenal perforations as well as free jejunal perforations during ERCP. Although ERCP-related duodenal perforations can result in a free perforation, most are retroperitoneal. Manifestations of such contained duodenal perforations following ERCP can resemble those of ERCP-induced pancreatitis, including hyperamylasemia.

CT scanning is the most sensitive test for diagnosing duodenal perforations; positive findings include pneumoperitoneum for free perforations, but more commonly retroperitoneal air, contrast extravasation, and paraduodenal fluid collections. If all patients undergoing a therapeutic ERCP are imaged with a CT scan following the procedure, up to 30% will have evidence of air in the retroperitoneum, but the majority are asymptomatic. These patients do not require any specific therapy.26

True cases of retroperitoneal perforations of the duodenum can be managed nonoperatively, in the absence of progression and sepsis. However, intraperitoneal duodenal perforations require surgical repair with pyloric exclusion and gastrojejunostomy or tube duodenostomy. Iatrogenic small bowel perforation incurred during endoscopy, if immediately recognized, can sometimes be repaired using endoscopic techniques.

Perforation of the jejunum and ileum occurs into the peritoneal cavity and usually causes overt symptoms and signs, such as abdominal pain, tenderness, and distention accompanied by fever and tachycardia. Plain abdominal radiographs may reveal free intraperitoneal air if intraperitoneal perforation has occurred. If perforation is suspected but not clinically obvious, CT scanning should be performed. Jejunal and ileal perforations require surgical repair or segmental resection.

**Chylous Ascites**

Chylous ascites refers to the accumulation of triglyceride-rich peritoneal fluid with a milky or creamy appearance, caused by the presence of intestinal lymph in the peritoneal cavity. Chylomicrons, produced by the intestine and secreted into lymph during the absorption of long-chain fatty acids, account for the characteristic appearance and triglyceride content of chyle.

The most common etiologies of chylous ascites in Western countries are abdominal malignancies and cirrhosis. In Eastern and developing countries, infectious etiologies, such as tuberculosis and filariasis, account for most cases. Chylous ascites can also develop as a complication of abdominal and thoracic operations and trauma. Operations particularly associated with this complication include abdominal aortic aneurysm repair, retroperitoneal lymph node dissection, inferior vena cava resection, and liver transplantation. Other etiologies of chylous ascites include congenital lymphatic abnormalities (e.g., primary lymphatic hypoplasia), radiation, pancreatitis, and right-sided heart failure.

Three mechanisms have been postulated to cause chylous ascites: (a) exudation of chyle from dilated lymphatics on the wall of the bowel and in the mesentery caused by obstruction of lymphatic vessels at the base of the mesentery or the cisterna chilii (e.g., by malignancies); (b) direct leakage of chyle through
a lymphoperitoneal fistula (e.g., those that develop as a result of trauma or surgery); and (c) exudation of chyle through the wall of dilated retroperitoneal lymphatic vessels (e.g., in congenital lymphangiectasia or thoracic duct obstruction).

Patients with chylous ascites develop abdominal distention over a period of weeks to months. Postoperative chylous ascites can present acutely during the first postoperative week. Delayed presentations following surgery can occur if the mechanism of ascites formation is adhesion-induced lymphatic obstruction rather than lymphatic vessel disruption. Dyspnea may result if abdominal distention is severe enough.

Paracentesis is the most important diagnostic test. Chyle typically has a cloudy and turbid appearance; however, it may be clear in fasting patients (such as those in the immediate postoperative period). Fluid triglyceride concentrations above 110 mg/dL are diagnostic. CT scanning may be useful in identifying pathologic intra-abdominal lymph nodes and masses and in identifying extent and localization of fluid. Lymphangiography and lymphoscintigraphy may help localize lymph leaks and obstruction; this information is particularly useful for surgical planning.

There are few data on optimal management of patients with chylous ascites. The general approach is to focus on evaluating and treating the underlying causes, especially for patients with infectious, inflammatory, or hemodynamic etiologies for this condition.

Most patients respond to administration of a high-protein and low-fat diet supplemented with medium-chain triglycerides. This regimen is designed to minimize chyle production and flow. Medium-chain triglycerides are absorbed by the intestinal epithelium and are transported to liver through the portal vein; they do not contribute to chylomicron formation.

Patients who do not respond to this approach should be fasted and placed on TPN. Octreotide can further decrease lymph flow. Paracentesis is indicated for respiratory difficulties related to abdominal distention. Overall, two thirds of patients will respond to conservative therapy. However, one third of patients will require surgical therapy for chylous ascites. In general, postoperative and trauma-related cases that fail to respond to initial nonoperative therapy are best managed by surgical repair. Lymphatic leaks are localized and repaired with fine nonabsorbable sutures. If extravasation of chyle is localized to the periphery of the small bowel mesentery, then a limited small bowel resection can be performed instead. For patients who are poor surgical candidates and do not respond to prolonged conservative therapy, peritoneovenous shunting may be an option. However, these shunts are associated with high rates of complications, including sepsis and disseminated intravascular coagulation. Because of the viscosity of chyle, these shunts are associated with a high occlusion rate.

**Intussusception**

Intussusception refers to a condition where one segment of the intestine becomes drawn in to the lumen of the proximal segment of the bowel. It is usually seen in the pediatric population, where the cecum intussuspects into the ileum (ileocolic intussusception). In children, it is often an idiopathic condition and treated nonsurgically by radiologic reduction.

Adult intussusceptions are far less common and usually have a distinct pathologic lead point, which can be malignant in up to one half of cases. They commonly present with a history of intermittent abdominal pain and signs and symptoms of bowel obstruction. CT scan is the investigation of choice, where a “target sign” may be seen (Fig. 28-30). Treatment is surgical resection of the involved segment and the lead point, which needs to undergo pathologic evaluation to rule out an underlying malignancy.

With increasing use of CT imaging, target signs are sometimes seen on CT scans of patients who do not have a clinical presentation indicative of bowel obstruction. In such cases, the finding is of little clinical significance and is probably related to normal peristalsis.

In patients who have undergone a Roux-en-Y gastric bypass surgery, an atypical form of intussusception has been increasingly described. In these cases, the proximal bowel is drawn in to the lumen of the distal bowel (retrograde intussusception). These intussusceptions are usually not associated with a lead point and may represent a motility disorder of the bowel following the Roux-en-Y reconstruction. Surgical reductions without resection have been successfully reported in these patients.

**Pneumatosis Intestinalis**

Pneumatosis intestinalis indicates the presence of gas within the bowel wall. It may affect any region of the GI tract, but is most

---

**Figure 28-30.** Small bowel intussusception. Panel A demonstrates the target sign seen on computed tomography scans in patients with small bowel intussusception (arrow). Panel B demonstrates the distal bowel clearly within the lumen of the proximal bowel (arrow).
commonly seen in the jejunum. Pneumatosis intestinalis is not a disease but merely a sign that can be idiopathic or associated with many intestinal or nonintestinal disorders such as obstructive pulmonary disease and asthma. Most cases of pneumatosis intestinalis are secondary to an identifiable cause, and 15% are idiopathic. The pathogenesis of pneumatosis intestinalis is not fully understood.

The surgical interest in this finding is the association of it with bowel ischemia and infarction, both of which necessitate emergent surgical intervention (see Fig. 28-15). Thus, patients with this radiologic finding need to be fully evaluated and monitored closely to rule out such intra-abdominal catastrophes.

**SHORT BOWEL SYNDROME**

Intestinal resection is performed for many of the diseases discussed in this chapter and generally is associated with minimal morbidity. However, when extent of resection is great enough, a devastating condition known as short bowel syndrome may result. Short bowel syndrome has been arbitrarily defined as the presence of less than 200 cm of residual small bowel in adult patients. A functional definition, in which insufficient intestinal absorptive capacity results in the clinical manifestations of diarrhea, dehydration, and malnutrition, is more broadly applicable.

In adults, the most common etiologies of short bowel syndrome are acute mesenteric ischemia, malignancy, and Crohn’s disease. Seventy-five percent of cases result from resection of a large amount of small bowel at a single operation. Twenty-five percent of cases result from the cumulative effects of multiple operations during which small intestine is resected. This latter pattern is typical of patients with Crohn’s disease who develop short bowel syndrome; the former is typical of patients with acute mesenteric ischemia who develop intestinal infarction. In pediatric patients, intestinal atresias, volvulus, and necrotizing enterocolitis are the most common etiologies of short bowel syndrome.

The prevalence of short bowel syndrome is hard to estimate. The most recent available data on chronic home total TPN administration were obtained in 1992. At that time, approximately 40,000 patients were receiving TPN chronically at home. The most prevalent indication for TPN among these patients was short bowel syndrome; however, this estimate does not include patients with short bowel syndrome not receiving TPN at home. It also fails to include those who have been weaned off of TPN.

**Pathophysiology**

Resection of less than 50% of the small intestine is generally well tolerated. However, clinically significant malabsorption occurs when greater than 50% to 80% of the small intestine has been resected. Among adult patients who lack a functional colon, lifelong TPN dependence is likely to persist if there is less than 100 cm of residual small intestine. Among adult patients who have an intact and functional colon, lifelong TPN dependence is likely to persist if there is less than 60 cm of residual small intestine. Among infants with short bowel syndrome, weaning from TPN dependence has been achieved with as little as 10 cm of residual small intestine.

Residual bowel length is not the only factor predictive of achieving independence from TPN (enteral autonomy), however. Other determinants of the severity of malabsorption include the presence or absence of an intact colon, as indicated earlier. The colon has the capacity to absorb large fluid and electrolyte loads. In addition, the colon can play an important, albeit small, role in nutrient assimilation by absorbing short-chain fatty acids. Second, an intact ileocecal valve is believed to be associated with decreased malabsorption. The ileocecal valve delays transit of chyme from the small intestine into the colon, thereby prolonging the contact time between nutrients and the small-intestinal absorptive mucosa. Third, healthy, rather than diseased, residual small intestine is associated with decreased severity of malabsorption. Fourth, resection of jejunum is better tolerated than resection of ileum, as the capacity for bile salt and vitamin B<sub>12</sub> absorption is specific to the ileum (Table 28-11).

During the first 1 to 2 years following massive small bowel resection, the remaining intestine undergoes compensatory adaptation, as discussed earlier. Clinically, the period of adaptation is associated with reductions in volume and frequency of bowel movements, increases in the capacity for enteral nutrient assimilation, and reductions in TPN requirements. As this process completes, some patients are successfully weaned off TPN. Understanding the mechanisms mediating intestinal adaptation may suggest strategies for enhancing adaptation in patients with short bowel syndrome who are unable to achieve independence from TPN. To date, the phenomenon of intestinal adaptation in patients remains poorly understood.

Malabsorption in patients who have undergone massive small bowel resection is exacerbated by a characteristic hypergastrinemia-associated gastric acid hypersecretion that persists for 1 to 2 years postoperatively. The increased acid load delivered to the duodenum inhibits absorption by a variety of mechanisms, including the inhibition of digestive enzymes, most of which function optimally under alkaline conditions.

**Therapy**

**Medical Therapy.** For patients having undergone massive small bowel resection, the initial treatment priorities include management of the primary condition precipitating the intestinal resection and the repletion of fluid and electrolytes lost in the severe diarrhea that characteristically occurs. Most patients will require TPN, at least initially. Enteral nutrition should be gradually introduced, once ileus has resolved. High-dose histamine-2 receptor antagonists or proton pump inhibitors should be administered to reduce gastric acid secretion. Antimotility agents, such as loperamide hydrochloride or diphenoxylate, may be administered to delay small-intestinal transit. Octreotide can be administered to reduce the volume of GI secretions, although in animal models, its use is associated with an inhibition of intestinal adaptation.

During the period of adaptation, generally lasting 1 to 2 years postoperatively, TPN and enteral nutrition are titrated
in an attempt to allow for independence from TPN. Patients who remain dependent on TPN face substantial TPN-associated morbidities including catheter sepsis, venous thrombosis, liver and kidney failure, and osteoporosis. Liver failure is a significant source of morbidity and often leads to liver transplantation (always in combination with small bowel transplantation). Due to these complications, patients with short bowel syndrome on TPN have a reduced life expectancy, with 5-year survival rates of 50% to 75%. Costs associated with chronic TPN administration are estimated to be as high as $150,000 per patient annually. Because of these problems, alternative therapies for short bowel syndrome are under investigation.

Nontransplant Surgical Therapy. Among patients with stomas, restoration of intestinal continuity should be performed whenever possible to capitalize on the absorptive capacity of all residual intestine. Other forms of nontransplant surgery designed to improve intestinal absorption are associated with unclear efficacy and/or substantial morbidities and therefore should not be applied routinely.

The goal of these operations is to increase nutrient and fluid absorption by either slowing intestinal transit or increasing intestinal length. Operations designed to slow intestinal transit include segmental reversal of the small bowel, interposition of a segment of colon between segments of small bowel, construction of small-intestinal valves, and electrical pacing of the small intestine. Reported experience with these procedures is limited to case reports or series of a few cases. Objective evidence of increased absorption is lacking; further, these procedures are frequently associated with intestinal obstruction.

The intestinal lengthening operation that has the longest history is the longitudinal intestinal lengthening and tailoring (LILT) procedure, first described by Bianchi in 1980. The procedure entails separation of the dual vasculature of the small intestine, followed by longitudinal division of the bowel with subsequent isoperistaltic end-to-end anastomosis. This procedure has the potential to double the length of small intestine to which it is applied. This procedure has generally been used for pediatric patients with dilated residual small bowel.

An alternative surgical approach to lengthening the small bowel is the serial transverse enteroplasty procedure (STEP). This procedure is designed to accomplish lengthening of dilated small intestine without the need for separating its dual vasculature (Fig. 28-31). A recent report from an international registry of 111 patients showed that 47% of patients achieved enteral autonomy at a median follow-up of 21 months.

Intestinal Transplantation. This complex procedure is being increasingly performed to treat patients with short bowel syndrome. Approximately 1850 patients worldwide had undergone this procedure by 2009. The currently accepted indication for intestinal transplantation is the presence of life-threatening complications attributable to intestinal failure and/or long-term TPN therapy. Specific complications for which intestinal transplantation is indicated include (a) impending or overt liver failure, (b) thrombosis of major central veins, (c) frequent episodes of catheter-related sepsis, and (d) frequent episodes of severe dehydration.

Of the transplants involving the intestine, 37% were intestine-alone transplants, 30% included intestine + liver + pancreas, and 24% were intestine + liver.

Isolated intestinal transplantation is used for patients with intestinal failure who have no significant liver disease or failure of other organs. Combined intestine/liver transplantation is used for patients with both intestinal and liver failure. Multivisceral transplantation has been used for patients with giant desmoid tumors involving the vascular supply of the liver and pancreas as well as that of the intestine, for diffuse GI motility disturbances, and for diffuse splanchic thrombosis.

Nearly 80% of survivors have full intestinal graft function with no need for TPN. However, morbidities associated with intestinal transplantation are substantial and include acute and chronic rejection, CMV infection, and postransplant lymphoproliferative disease.

Alternative Therapies. Pharmacologic and biologic therapies designed to expand intestinal mucosal surface area or to enhance the efficiency of intestinal absorption are beginning to undergo clinical evaluation. Promising regimens include GLP-2 and the combination of glutamine and growth hormone with a modified, high-carbohydrate diet.

Outcomes
Approximately 50% to 70% of patients with short bowel syndrome who initially require TPN are ultimately able to

Figure 28-31. This figure depicts the serial transverse enteroplasty (STEP) procedure. Lengthening of dilated small intestine is accomplished by serial applications of an intestinal stapling device, with firings oriented perpendicular to the long axis of the intestine. (Used with permission from Patrick Javid, MD, and Tom Jaksic, MD, Department of Surgery, Children’s Hospital, Boston, MA).
achieve independence from TPN. Prognosis for achieving enteral autonomy is better among pediatric patients than among adults.

Information on survival among patients with short bowel syndrome is limited. In a recently reported study of 124 adults with short bowel syndrome due to nonmalignant etiologies, the survival rates at 2 and 5 years of follow-up were 86% and 45%, respectively. Patients with end-enterostomies and those having less than 50 cm of residual small intestine had significantly worse survivals than those without these features.

No randomized trials comparing intestinal transplantation to chronic TPN administration among patients with short bowel syndrome have been reported. One-, 5-, and 10-year graft survivals were 89%, 80%, and 79%, respectively. +26%; whereas the rates for intestine syndrome have been reported. One-, 5-, and 10-year graft survivals were 86% and 45%, respectively.

EMBRYOLOGY AND ANATOMY

Embryology
The embryonic gastrointestinal tract begins developing during the fourth week of gestation. The primitive gut is derived from the endoderm and divided into three segments: foregut, midgut, and hindgut. Both midgut and hindgut contribute to the colon, rectum, and anus.

The midgut develops into the small intestine, ascending colon, and proximal transverse colon, and receives blood supply from the superior mesenteric artery. During the sixth week of gestation, the midgut herniates out of the abdominal cavity, and then rotates 270° counterclockwise around the superior mesenteric artery to return to its final position inside the abdominal cavity during the tenth week of gestation. The hindgut develops into the distal transverse colon, descending colon, rectum, and...
The large intestine extends from the ileocecal valve to the anus. It is divided anatomically and functionally into the colon, rectum, and anal canal. The wall of the colon and rectum comprise five distinct layers: mucosa, submucosa, inner circular muscle, outer longitudinal muscle, and serosa. In the colon, the outer longitudinal muscle is separated into three teniae coli, which converge proximally at the appendix and distally at the rectum, where the outer longitudinal muscle layer is circumferential. In the distal rectum, the inner smooth muscle layer coalesces to form the internal anal sphincter. The intraperitoneal colon and proximal one-third of the rectum are covered by serosa; the mid and lower rectum lack serosa.

**Colon Landmarks.** The colon begins at the junction of the terminal ileum and cecum and extends 3 to 5 feet to the rectum. The rectosigmoid junction is found at approximately the level of the sacral promontory and is arbitrarily described as the point at which the three teniae coli coalesce to form the outer longitudinal smooth muscle layer of the rectum. The cecum is the widest diameter portion of the colon (normally 7.5–8.5 cm) and has the thinnest muscular wall. As a result, the cecum is most vulnerable to perforation and least vulnerable to obstruction. The ascending colon is usually fixed to the retroperitoneum.

The hepatic flexure marks the transition to the transverse colon.

The arterial supply to the colon is provided by several sigmoidal branches of the inferior mesenteric artery. During the sixth week of gestation, the distal-most end of the hindgut, the cloaca, is divided by the urorectal septum into the urogenital sinus and the rectum.

The distal anal canal is derived from ectoderm and receives its blood supply from the internal pudendal artery. The dentate line divides the endodermal hindgut from the ectodermal distal anal canal.

**Anatomy**

The arterial supply to the colon is provided by several sigmoidal branches of the inferior mesenteric artery. During the sixth week of gestation, the distal-most end of the hindgut, the cloaca, is divided by the urorectal septum into the urogenital sinus and the rectum.

The distal anal canal is derived from ectoderm and receives its blood supply from the internal pudendal artery. The dentate line divides the endodermal hindgut from the ectodermal distal anal canal.

**Colon Landmarks.** The colon begins at the junction of the terminal ileum and cecum and extends 3 to 5 feet to the rectum. The rectosigmoid junction is found at approximately the level of the sacral promontory and is arbitrarily described as the point at which the three teniae coli coalesce to form the outer longitudinal smooth muscle layer of the rectum. The cecum is the widest diameter portion of the colon (normally 7.5–8.5 cm) and has the thinnest muscular wall. As a result, the cecum is most vulnerable to perforation and least vulnerable to obstruction. The ascending colon is usually fixed to the retroperitoneum.

The hepatic flexure marks the transition to the transverse colon.

The intraperitoneal transverse colon is relatively mobile, but is tethered by the gastrocolic ligament and colonic mesentery. The greater omentum is attached to the anterior/superior edge of the transverse colon. These attachments explain the characteristic triangular appearance of the transverse colon observed during colonoscopy. The splenic flexure marks the transition from the transverse colon to the descending colon. The attachments between the splenic flexure and the spleen (the lienocolic ligament) can be short and dense, making mobilization of this flexure during colectomy challenging. The descending colon is relatively fixed to the retroperitoneum. The sigmoid colon is the narrowest part of the large intestine and is extremely mobile. Although the sigmoid colon is usually located in the left lower quadrant, redundancy and mobility can result in a portion of the sigmoid colon residing in the right lower quadrant. This mobility explains why volvulus is most common in the sigmoid colon and why diseases affecting the sigmoid colon, such as diverticulitis, may occasionally present as right-sided abdominal pain. The narrow caliber of the sigmoid colon makes this segment of the large intestine the most vulnerable to obstruction.

**Colon Vascular Supply.** The arterial supply to the colon is highly variable (Fig. 29-1). In general, the superior mesenteric artery branches into the ileocolic artery (absent in up to 20% of people), which supplies blood to the terminal ileum and proximal ascending colon; the right colic artery, which supplies the ascending colon; and the middle colic artery, which supplies the transverse colon. The inferior mesenteric artery branches into the left colic artery, which supplies the descending colon; several sigmoidal branches, which supply the sigmoid colon; and the superior rectal artery, which supplies the proximal rectum. The terminal branches of each artery form Anastomoses with the terminal branches of the adjacent artery and communicate

---

**Key Points**

1. Resection principles: The mesenteric clearance technique dictates the extent of resection and is determined by the nature of the primary pathology, the intent of resection, the location of the lesion, and the condition of the mesentery.

2. Function after resection: Bowel function is often compromised after colorectal resection, especially after low anterior resection. For this reason, it is important to obtain a history of prior anorectal trauma and/or incontinence before considering a low anastomosis.

3. Ostomies: Preoperative marking for a planned stoma is critical for a patient’s quality of life. Ideally, a stoma should be located within the rectus muscle, in a location where the patient can easily see and manipulate the appliance, and away from previous scars, bony prominences, or abdominal creases.

4. Inflammatory bowel disease: Both Crohn’s disease and ulcerative colitis are associated with an increased risk of colorectal cancer. Risk depends on the amount of colon involved and the duration of disease.

5. Pathogenesis of colorectal cancer: A variety of mutations have been identified in colorectal cancer. Mutations may cause activation of oncogenes (K-ras) and/or inactivation of tumor suppressor genes (adenomatous polyposis coli [APC], deleted in colorectal carcinoma [DCC], p53).

6. Minimally invasive resection: Laparoscopy and HAL have been shown to be both safe and efficacious for colorectal resection.

7. Anal epidermoid carcinoma: Unlike rectal adenocarcinoma, anal epidermoid carcinoma is treated primarily with chemoradiation. Surgery is reserved for patients with persistent or recurrent disease.

8. Rectal prolapse: Rectal prolapse occurs most commonly in elderly women. Transabdominal repair (rectopexy with or without resection) offers more durability than perineal proctosigmoidectomy, but carries greater operative risk.

9. Hemorrhoids: Hemorrhoids are cushions of submucosal tissue containing venules, arterioles, and smooth muscle fiber. They are thought to play a role in maintaining continence. Resection is only indicated for refractory symptoms.

10. Fistula in ano: Treatment of fistula in ano depends on the location of the fistula, amount of anal sphincter involved in the fistula, and the underlying disease process.
via the marginal artery of Drummond. This arcade is complete in only 15% to 20% of people.

Except for the inferior mesenteric vein, the veins of the colon parallel their corresponding arteries and bear the same terminology (Fig. 29-2). The inferior mesenteric vein ascends in the retroperitoneal plane over the psoas muscle and continues posterior to the pancreas to join the splenic vein. During a colectomy, this vein is often mobilized independently and ligated at the inferior edge of the pancreas.

**Colon Lymphatic Drainage.** The lymphatic drainage of the colon originates in a network of lymphatics in the muscularis mucosa. Lymphatic vessels and lymph nodes follow the regional arteries. Lymph nodes are found on the bowel wall (epicolic), along the inner margin of the bowel adjacent to the arterial arcades (paracolic), around the named mesenteric vessels (intermediate), and at the origin of the superior and inferior mesenteric arteries (main). The sentinel lymph nodes are the first one to four lymph nodes to drain a specific segment of the colon and are thought to be the first site of metastasis in colon cancer. The utility of sentinel lymph node dissection and analysis in colon cancer remains controversial.

**Colon Nerve Supply.** The colon is innervated by both sympathetic (inhibitory) and parasympathetic (stimulatory) nerves, which parallel the course of the arteries. Sympathetic nerves arise from T6-T12 and L1-L3. The parasympathetic innervation to the right and transverse colon is from the vagus nerve; the parasympathetic nerves to the left colon arise from sacral nerves S2-S4 to form the nervi erigentes.

**Anorectal Landmarks.** The rectum is approximately 12 to 15 cm in length. Three distinct submucosal folds, the valves of Houston, extend into the rectal lumen. Posteriorly, the presecral fascia separates the rectum from the presacral venous plexus and the pelvic nerves. At S4, the rectosacral fascia (Waldeyer’s fascia) extends forward and downward and attaches to the fascia propria at the anorectal junction. Anteriorly, Denonvilliers’ fascia separates the rectum from the prostate and seminal vesicles in men and from the vagina in women. The lateral ligaments support the lower rectum.

The anatomic anal canal extends from the dentate or pectinate line to the anal verge. The dentate or pectinate line marks the transition point between columnar rectal mucosa and squamous anoderm. The anal transition zone includes mucosa proximal to the dentate line that shares histologic characteristics of columnar, cuboidal, and squamous epithelium. Although the anal transition zone was long thought to extend only 1 to 2 cm proximal to the dentate line, it is known that the proximal extent of this zone is highly variable and can be as far as 15 cm proximal to
the dentate line. The dentate line is surrounded by longitudinal mucosal folds, known as the *columns of Morgagni*, into which the anal crypts empty. These crypts are the source of cryptoglandular abscesses (Fig. 29-3). In contrast to the anatomic anal canal, the surgical anal canal begins at the anorectal junction and terminates at the anal verge. The surgical anal canal measures 2 to 4 cm in length and is generally longer in men than in women. It begins at the anorectal junction and terminates at the anal verge.

In the distal rectum, the inner smooth muscle is thickened and comprises the *internal anal sphincter* that is surrounded by the subcutaneous, superficial, and deep external sphincter. The deep external anal sphincter is an extension of the *puborectalis muscle*. The *puborectalis*, *iliococcygeus*, and *pubococcygeus* muscles form the *levator ani muscle* of the pelvic floor (Fig. 29-4).

**Anorectal Vascular Supply.** The *superior rectal artery* arises from the terminal branch of the inferior mesenteric artery and supplies the upper rectum. The *middle rectal artery* arises from the internal iliac; the presence and size of these arteries are highly variable. The *inferior rectal artery* arises from the internal pudendal artery, which is a branch of the internal iliac artery. A rich network of collaterals connects the terminal arterioles of each of these arteries, thus making the rectum relatively resistant to ischemia (Fig. 29-5).

The venous drainage of the rectum parallels the arterial supply. The *superior rectal vein* drains into the portal system via the inferior mesenteric vein. The *middle rectal vein* drains into the internal iliac vein. The *inferior rectal vein* drains into the internal pudendal vein, and subsequently into the internal iliac vein. A submucosal plexus deep to the columns of Morgagni forms the *hemorrhoidal plexus* and drains into all three veins.

**Anorectal Lymphatic Drainage.** Lymphatic drainage of the rectum parallels the vascular supply. Lymphatic channels in the upper and middle rectum drain superiorly into the inferior
mesenteric lymph nodes. Lymphatic channels in the lower rectum drain both superiorly into the inferior mesenteric lymph nodes and laterally into the internal iliac lymph nodes. The anal canal has a more complex pattern of lymphatic drainage. Proximal to the dentate line, lymph drains into both the inferior mesenteric lymph nodes and the internal iliac lymph nodes. Distal to the dentate line, lymph primarily drains into the inguinal lymph nodes, but can also drain into the inferior mesenteric lymph nodes and internal iliac lymph nodes.

Anorectal Nerve Supply. Both sympathetic and parasympathetic nerves innervate the anorectum. Sympathetic nerve fibers are derived from L1-L3 and join the preaortic plexus. The preaortic nerve fibers then extend below the aorta to form the hypogastric plexus, which subsequently joins the parasympathetic fibers to form the pelvic plexus. Parasympathetic nerve fibers are known as the neri erigentes and originate from S2-S4. These fibers join the sympathetic fibers to form the pelvic plexus. Sympathetic and parasympathetic fibers then supply the anorectum and adjacent urogenital organs.

The internal anal sphincter is innervated by sympathetic and parasympathetic nerve fibers: both types of fibers inhibit sphincter contraction. The external anal sphincter and puborectalis muscles are innervated by the inferior rectal branch of the internal pudendal nerve. The levator ani receives innervation from both the internal pudendal nerve and direct branches of S3 to S5. Sensory innervation to the anal canal is provided by the inferior rectal branch of the pudendal nerve. While the rectum is relatively insensitive, the anal canal below the dentate line is sensitive.

Congenital Anomalies
Perturbation of the embryologic development of the midgut and hindgut may result in anatomic abnormalities of the colon, rectum, and anus. Failure of the midgut to rotate and return to the abdominal cavity during the tenth week of gestation results in varying degrees of intestinal malrotation and colonic nonfixation. Failure of canalization of the primitive gut can result in colonic duplication. Incomplete descent of the urogenital septum may result in imperforate anus and associated fistulas to the genitourinary tract. Many infants with congenital anomalies of the hindgut have associated abnormalities in the genitourinary tract.

NORMAL PHYSIOLOGY
Fluid and Electrolyte Exchanges
Water, Sodium, Potassium, Chloride, Bicarbonate, and Ammonia. The colon is a major site for water absorption and electrolyte exchange. Under normal circumstances, approximately 90% of the water contained in ileal fluid is absorbed in the colon (1000–2000 mL/d), but up to 5000 mL of fluid can be absorbed daily. Sodium is absorbed actively via sodium-potassium (Na+,K+) ATPase. The colon can absorb up to 400 mEq of sodium per day. Water accompanies the transported sodium and is absorbed passively along an osmotic gradient. Potassium is actively secreted into the colonic lumen and absorbed by passive diffusion. Chloride is absorbed actively via a chloride-bicarbonate exchange.

Bacterial degradation of protein and urea produces ammonia. Ammonia is subsequently absorbed and transported to the liver. Absorption of ammonia depends in part on intraluminal pH. A decrease in colonic bacteria (e.g., due to broad-spectrum antibiotic use) and/or a decrease in intraluminal pH (e.g., due to lactulose administration) will decrease ammonia absorption.

Short-Chain Fatty Acids
Short-chain fatty acids (acetate, butyrate, and propionate) are produced by bacterial fermentation of dietary carbohydrates. Short-chain fatty acids are an important source of energy for the colonic mucosa, and metabolism by colonocytes provides energy for processes such as active transport of sodium. Lack of a dietary source for production of short-chain fatty acids, or diversion of the fecal stream by an ileostomy or colostomy, may result in mucosal atrophy and inflammation, the latter termed “diversion colitis.”

Colonic Microflora and Intestinal Gas
Approximately 30% of fecal dry weight is composed of bacteria (10^11–10^12 bacteria/g of feces). Anaerobes are the predominant class of microorganism, and Bacteroides species are the most common (10^11–10^12 organisms/mL). Escherichia coli are the most numerous aerobes (10^8–10^9 organisms/mL). Endogenous microflora are crucial for the breakdown of carbohydrates and proteins in the colon and participate in the metabolism of bilirubin, bile acids, estrogen, and cholesterol. Colonic bacteria also are necessary for production of vitamin K. Endogenous bacteria also are thought to suppress the emergence of pathogenic microorganisms, such as Clostridium difficile, a phenomenon termed “colonization resistance.” However, the high bacterial load of the large intestine may contribute to sepsis and/or abscess formation, and wound infection following colectomy.

Intestinal gas arises from swallowed air, diffusion from the blood, and intraluminal production. Nitrogen, oxygen, carbon dioxide, hydrogen, and methane are the major components of intestinal gas. Nitrogen and oxygen are largely derived from swallowed air. Carbon dioxide is produced by the reaction of bicarbonate and hydrogen ions and by the digestion of triglycerides to fatty acids. Hydrogen and methane are produced by colonic bacteria. The production of methane is highly variable. The gastrointestinal tract usually contains between 100 and 200 mL of gas, and 400 to 1200 mL/d are released as flatus, depending on the type of food ingested.
Motility, Defecation, and Continence

Motility. Unlike the small intestine, the large intestine does not demonstrate cyclic motor activity characteristic of the migratory motor complex. Instead, the colon displays intermittent contractions of either low or high amplitude. Low-amplitude, short-duration contractions occur in bursts and appear to move the colonic contents both antegrade and retrograde. It is thought that these bursts of motor activity delay colonic transit and thus increase the time available for absorption of water and exchange of electrolytes. High-amplitude contractions occur in a more coordinated fashion and create “mass movements.” Bursts of “rectal motor complexes” also have been described. In general, cholinergic activation increases colonic motility.

Defecation. Defecation is a complex, coordinated mechanism involving colonic mass movement, increased intra-abdominal and rectal pressure, and relaxation of the pelvic floor. Distention of the rectum causes a reflex relaxation of the internal anal sphincter (the rectoanal inhibitory reflex) that allows the contents to make contact with the anal canal. This “sampling reflex” allows the sensory epithelium to distinguish solid stool from liquid stool and gas. If defecation does not occur, the rectum relaxes and the urge to defecate passes (*accommodation response*). Defecation proceeds by coordination of increasing intra-abdominal pressure via the Valsalva maneuver, increased rectal contraction, relaxation of the puborectalis muscle, and opening of the anal canal.

Continence. The maintenance of fecal continence is at least as complex as the mechanism of defecation. Continence requires adequate rectal wall compliance to accommodate the fecal bolus, appropriate neurogenic control of the pelvic floor and sphincter mechanism, and functional internal and external sphincter muscles. At rest, the puborectalis muscle creates a “sling” around the distal rectum, forming a relatively acute angle that distributes intra-abdominal forces onto the pelvic floor. With defecation, this angle straightens, allowing downward force to be applied along the axis of the rectum and anal canal. The internal and external sphincters are tonically active at rest. The internal sphincter is responsible for most of the resting, involuntary sphincter tone (resting pressure). The external sphincter is responsible for most of the voluntary sphincter tone (squeeze pressure). Branches of the pudendal nerve innervate both the internal and external sphincter. Finally, the hemorrhoidal cushions may contribute to continence by mechanically blocking the anal canal. Thus, impaired continence may result from poor rectal compliance, injury to the internal and/or external sphincter or puborectalis, or nerve damage or neuropathy.

CLINICAL EVALUATION

Clinical Assessment

Obtaining a complete history and performing a physical examination are the starting points for evaluating any patient with suspected disease of the colon, rectum, or anus. Special attention should be paid to the patient's past medical and surgical history to detect underlying conditions that might contribute to a gastrointestinal problem. If patients have had prior intestinal surgery, it is essential that one understand the resultant gastrointestinal anatomy. A history of anorectal surgery may be critical for patients with either abdominal or anorectal complaints. The obstetrical history in women is essential to detect occult pelvic floor and/or anal sphincter damage. Identifying a family history of colorectal disease, especially inflammatory bowel disease, polyps, and colorectal cancer, is crucial. In addition to a family history of colorectal disease, a history of other malignancies may suggest the presence of a genetic syndrome. Medication use must be detailed as many drugs cause gastrointestinal symptoms. Before recommending operative intervention, the adequacy of medical treatment must be ascertained. In addition to examining the abdomen, visual inspection of the anus and perineum and careful digital rectal exam are essential.

Endoscopy

Anoscopy. The anoscope is a useful instrument for examination of the anal canal. Anoscopes are made in a variety of sizes and measure approximately 8 cm in length. A larger anoscope provides better exposure for anal procedures such as rubber band ligation or sclerotherapy of hemorrhoids. The anoscope, with obturator in place, should be adequately lubricated and gently inserted into the anal canal. The obturator is withdrawn, inspection of the visualized anal canal is done, and the anoscopy should then be withdrawn. It is rotated 90° and reinserted to allow visualization of all four quadrants of the canal. If the patient complains of severe perianal pain and cannot tolerate a digital rectal examination, anoscopy should not be attempted without anesthesia.

Proctoscopy. The rigid proctoscope is useful for examination of the rectum and distal sigmoid colon and is occasionally used therapeutically. The standard proctoscope is 25 cm in length and available in various diameters. Most often, a 15- or 19-mm diameter proctoscope is used for diagnostic examinations. The large (25-mm diameter) proctoscope is useful for procedures such as polypectomy, electrocoagulation, or detorsion of a sigmoid volvulus. A smaller “pediatric” proctoscope (11-mm diameter) is better tolerated by patients with anal stricture. Suction is necessary for an adequate proctoscopic examination.

Flexible Sigmoidoscopy and Colonoscopy. Video or fiberoptic flexible sigmoidoscopy and colonoscopy provide excellent visualization of the colon and rectum. Sigmoidoscopes measure 60 cm in length. Full depth of insertion may allow visualization as high as the splenic flexure, although the mobility and redundancy of the sigmoid colon often limit the extent of the examination. Partial preparation with enemas is usually adequate for sigmoidoscopy, and most patients can tolerate this procedure without sedation. Colonoscopes measure 100 to 160 cm in length and are capable of examining the entire colon and terminal ileum. A complete oral bowel preparation is usually necessary for colonoscopy, and the duration and discomfort of the procedure usually require conscious sedation. Both sigmoidoscopy and colonoscopy can be used diagnostically and therapeutically. Electrocautery should generally not be used in the absence of a complete bowel preparation because of the risk of explosion of intestinal methane or hydrogen gases. Diagnostic colonoscopes possess a single channel through which instruments such as snares, biopsy forceps, or electrocautery can be passed; this channel also provides suction and irrigation capability. Therapeutic colonoscopes possess two channels to allow simultaneous suction/irrigation and the use of snares, biopsy forceps, or electrocautery.

Capsule Endoscopy. Capsule endoscopy is an emerging technology that uses a small ingestible camera. After swallowing the camera, images of the mucosa of the gastrointestinal tract are captured, transmitted by radiofrequency to a belt-held receiver,
and then downloaded to a computer for viewing and analysis. Capsule endoscopy largely has been used to detect small bowel lesions. However, it has been suggested that this technique might also be useful for diagnosing colorectal disease, although utility in the evaluation of colorectal disease remains unproven. Finally, recent advances in the development of maneuverable capsules may improve the sensitivity of this procedure.

**Imaging**

**Plain X-Rays and Contrast Studies.** Despite advanced radiologic techniques, plain X-rays and contrast studies continue to play an important role in the evaluation of patients with suspected colon and rectal diseases. Plain X-rays of the abdomen (supine, upright, and diaphragmatic views) are useful for detecting free intra-abdominal air, bowel gas patterns suggestive of small or large bowel obstruction, and volvulus. Contrast studies are useful for evaluating obstructive symptoms, delineating fistulous tracts, and diagnosing small perforations or anastomotic leaks. Although Gastrografin cannot provide the mucosal detail required for evaluating the integrity of the submucosal layer, it is useful for detecting extraluminal abnormalities, such as intra-abdominal abscesses and pericolic inflammation, and in staging colorectal carcinoma, because of its sensitivity in detection of hepatic metastases.

Detection of small lesions can be extremely difficult, especially in a patient with extensive diverticulosis. For this reason, a colonoscopy is preferred for evaluating nonobstructing mass lesions in the colon. Double-contrast barium enema has been used as a back-up examination if colonoscopy is incomplete.

**Computed Tomography.** Computed tomography (CT) commonly is employed in the evaluation of patients with abdominal complaints. Its utility is primarily in the detection of extraluminal disease, such as intra-abdominal abscesses and pericolic inflammation, and in staging colorectal carcinoma, because of its sensitivity in detection of hepatic metastases. Extravasation of oral or rectal contrast may also confirm the diagnosis of perforation or anastomotic leak. Nonspecific findings such as bowel wall thickening or mesenteric stranding may suggest inflammatory bowel disease, enteritis/colitis, or ischemia. A standard CT scan is relatively insensitive for the detection of intraluminal lesions; however, improved CT technology is increasing the ability to assess bulky rectal tumors and perirectal adenopathy.

**Computed Tomography Colonography.** CT colonography (virtual colonoscopy) is a radiologic technique that is designed to overcome some of the limitations of traditional CT scanning. This technology uses helical CT and three-dimensional reconstruction to detect intraluminal colonic lesions. Oral bowel preparation, oral and rectal contrast, and colon insufflation have been used to maximize sensitivity. Experience with this technology has shown a sensitivity and specificity for detecting 1 cm or larger polyps of 85% to 90% in most studies, making it comparable to traditional colonoscopy. The addition of “fecal tagging” agents that create a distinct difference in appearance between stool and mucosa during imaging studies holds promise for increasing accuracy and possibly decreasing the need for mechanical bowel preparation.

**Magnetic Resonance Imaging.** The main use of magnetic resonance imaging (MRI) in colorectal disorders is in evaluation of pelvic lesions. MRI is more sensitive than CT for detecting bony involvement or pelvic sidewall extension of rectal tumors. MRI accurately determines the extent of spread of rectal cancer into the adjacent mesorectum and can reliably predict difficulty achieving radial margin clearance of a rectal cancer by surgery alone. When the radial margin is threatened, neoadjuvant chemoradiation is generally indicated. MRI also can be helpful in the detection and delineation of complex fistulas in ano. The use of an endorectal coil may increase sensitivity.

**Positron Emission Tomography.** Positron emission tomography (PET) is used for imaging tissues with high levels of anaerobic glycolysis, such as malignant tumors. 

**Angiography.** Angiography is occasionally used for the detection of bleeding within the colon or small bowel. To visualize hemorrhage angiographically, bleeding must be relatively brisk (approximately 0.5 to 1.0 mL per minute). If extravasation of contrast is identified, infusion of vasopressin or angiographic embolization can be therapeutic. If surgical resection is required, the angiographic catheter can be left in place to assist with identification of the bleeding site intraoperatively.

CT and magnetic resonance angiography are also useful for assessing patency of visceral vessels. This technique uses three-dimensional reconstruction to detect vascular lesions. If an abnormality is found, more traditional techniques (angiography, surgery) may then be used to further define and/or correct the problem.

**Endorectal and Endoanal Ultrasound.** Endorectal ultrasound is primarily used to evaluate the depth of invasion of neoplastic lesions in the rectum. The normal rectal wall appears as a five-layer structure (Fig. 29-6). Ultrasound can reliably differentiate most benign polyps from invasive tumors based on the integrity of the submucosal layer. Ultrasound can also differentiate superficial T1-T2 from deeper T3-T4 tumors. Overall, the accuracy of ultrasound in detecting depth of mural invasion ranges between 81% and 94%. This modality also can detect enlarged perirectal lymph nodes, which may suggest nodal metastases; accuracy of detection of pathologically positive lymph nodes is 58% to 83%. Ultrasound may also prove useful for early detection of local recurrence after surgery.

Endoanal ultrasound is used to evaluate the layers of the anal canal. Internal anal sphincter, external anal sphincter, and puborectalis muscle can be differentiated. Endoanal ultrasound is particularly useful for detecting sphincter defects and for outlining complex anal fistulas.

**Physiologic and Pelvic Floor Investigations**

Anorectal physiologic testing uses a variety of techniques to investigate the function of the pelvic floor. These techniques are useful in the evaluation of patients with incontinence, constipation, rectal prolapse, obstructed defecation, and other disorders of the pelvic floor.

**Manometry.** Anorectal manometry is performed by placing a pressure-sensitive catheter in the lower rectum. The catheter is
then withdrawn through the anal canal and pressures recorded. A balloon attached to the tip of the catheter also can be used to test anorectal sensation. The resting pressure in the anal canal reflects the function of the internal anal sphincter (normal, 40–80 mmHg), whereas the squeeze pressure, defined as the maximum voluntary contraction pressure minus the resting pressure, reflects function of the external anal sphincter (normal, 40–80 mmHg above resting pressure). The high-pressure zone estimates the length of the anal canal (normal, 2.0–4.0 cm). The rectoanl inhibitory reflex can be detected by inflating a balloon in the distal rectum; absence of this reflex is characteristic of Hirschsprung’s disease.

Neurophysiology. Neurophysiologic testing assesses function of the pudendal nerves and recruitment of puborectalis muscle fibers. Pudendal nerve terminal motor latency measures the speed of transmission of a nerve impulse through the distal pudendal nerve fibers (normal, 1.8–2.2 ms); prolonged latency suggests the presence of neuropathy. Electromyographic (EMG) recruitment assesses the contraction and relaxation of the puborectalis muscle during attempted defecation. Normally, recruitment increases when a patient is instructed to “squeeze” and decreases when a patient is instructed to “push.” Inappropriate recruitment is an indication of paradoxical contraction (nonrelaxation of the puborectalis). Needle EMG has been used to map both the pudendal nerves and the anatomy of the internal and external sphincters. However, this examination is painful and poorly tolerated by most patients. Needle EMG has largely been replaced by pudendal nerve motor latency testing to assess pudendal nerve function and endoanal ultrasonography to map the sphincters.

Rectal Evacuation Studies. Rectal evacuation studies include the balloon expulsion test and video defecography. Balloon expulsion assesses a patient’s ability to expel an intrarectal balloon. Video defecography provides a more detailed assessment of defecation. In this test, barium paste is placed in the rectum, and defecation is then recorded fluoroscopically. Defecography is used to differentiate nonrelaxation of the puborectalis, obstructed defecation, increased perineal descent, rectal prolapse and intussusception, rectocele, and enterocele. The addition of vaginal contrast and intraperitoneal contrast is useful in delineating complex disorders of the pelvic floor.

Laboratory Studies

Fecal Occult Blood Testing. Fecal occult blood testing (FOBT) has been used as a screening test for colonic neoplasms in asymptomatic, average-risk individuals. The efficacy of this test is based on serial testing because the majority of colorectal malignancies will bleed intermittently. FOBT has been a nonspecific test for peroxidase contained in hemoglobin; consequently, occult bleeding from any gastrointestinal source will produce a positive result. Similarly, many foods (red meat, some fruits and vegetables, and vitamin C) will produce a false-positive result. Increased specificity is now possible by using immunochromic FOBT. These tests rely on monoclonal or polyclonal antibodies to react with the intact globin portion of human hemoglobin and are more specific for identifying occult bleeding from the colon or rectum. Any positive FOBT mandates further investigation, usually by colonoscopy.

Stool Studies. Stool studies are often helpful in evaluating the etiology of diarrhea. Wet-mount examination reveals the presence of fecal leukocytes, which may suggest colonic inflammation or the presence of an invasive organism such as invasive E. coli or Shigella species. Stool cultures can detect pathogenic bacteria, ova, and/or parasites. C. difficile colitis is diagnosed by detecting bacterial toxin in the stool. Steatorrhea may be diagnosed by adding Sudan red stain to a stool sample.

Serum Tests. Specific laboratory tests that should be performed will be dictated by the clinical scenario. Preoperative studies generally include a complete blood count and electrolyte panel. The addition of coagulation studies, liver function tests, and blood typing/cross-matching depends on the patient’s medical condition and the proposed surgical procedure.

Tumor Markers. Carcinoembryonic antigen (CEA) may be elevated in 60% to 90% of patients with colorectal cancer. Despite this, CEA is not an effective screening tool for this malignancy. Many practitioners follow serial CEA levels after curative-intent surgery in order to detect early recurrence of
colorectal cancer. However, this tumor marker is nonspecific, and no survival benefit has yet been proven. It is also important to note that CEA may be mildly elevated in patients who smoke tobacco. Other biochemical markers (ornithine decarboxylase, urokinase) have been proposed, but none has yet proven sensitive or specific for detection, staging, or predicting prognosis of colorectal carcinoma.  

**Genetic Testing.** Although familial colorectal cancer syndromes, such as familial adenomatous polyposis (FAP) and hereditary nonpolyposis colon cancer (HNPCC) are rare, information about the specific genetic abnormalities underlying these disorders has led to significant interest in the role of genetic testing for colorectal cancer.  

Tests for mutations in the adenomatous polyposis coli (APC) gene responsible for FAP and in mismatch repair genes responsible for HNPCC are commercially available and extremely accurate in families with known mutations. However, in the absence of an identified mutation, a negative result is uninformative. For individuals from high-risk families without an identified mutation, increased surveillance is recommended.  

Although many of these mutations are also present in sporadic colorectal cancer, the accuracy of genetic testing in average-risk individuals is considerably lower, and these tests are not recommended for screening. Because of the potential psychosocial implications of genetic testing, it is strongly recommended that professional genetic counselors be involved in the care of any patient considering these tests.  

**Evaluation of Common Symptoms**  

**Abdominal Pain.** Abdominal pain is a nonspecific symptom with myriad causes. Abdominal pain related to the colon and rectum can result from obstruction (either inflammatory or neoplastic), inflammation, perforation, or ischemia. Plain X-rays and judicious use of contrast studies and/or a CT scan can often confirm the diagnosis. Gentle retrograde contrast studies (Gastrografin enema) may be useful in delineating the degree of colonic obstruction. Sigmoidoscopy and/or colonoscopy performed by an experienced endoscopist can assist in the diagnosis of ischemic colitis, infectious colitis, and inflammatory bowel disease. However, if perforation or near complete obstruction is suspected, colonoscopy and/or sigmoidoscopy are generally contraindicated. Evaluation and treatment of abdominal pain from a colorectal source should follow the usual surgical principles of a thorough history and physical examination, appropriate diagnostic tests, resuscitation, and appropriately timed surgical intervention.  

**Pelvic Pain.** Pelvic pain can originate from the distal colon and rectum or from adjacent urogenital structures. Tenesmus may result from proctitis or from a rectal or retrorectal mass. Cyclical pain associated with menses, especially when accompanied by rectal bleeding, suggests a diagnosis of endometriosis. Pelvic inflammatory disease also can produce significant abdominal and pelvic pain. The extension of a peridiverticular abscess or periappendiceal abscess into the pelvis may also cause pain. CT scan and/or MRI may be useful in differentiating these diseases. Proctoscopy (if tolerated) also can be helpful. Occasionally, laparoscopy will yield a diagnosis.  

**Anorectal Pain.** Anorectal pain is most often secondary to an anal fissure, perirectal abscess and/or fistula, or a thrombosed hemorrhoid. Physical examination can usually differentiate these conditions. Other, less common causes of anorectal pain include anal canal neoplasms, perianal skin infection, and dermatologic conditions. Proctalgia fugax results from levator spasm and may present without any other anorectal findings. Physical exam is critical in evaluating patients with anorectal pain. If a patient is too tender to examine in the office, an examination under anesthesia is necessary. MRI or other imaging studies may be helpful in select cases where the etiology of pain is elusive.  

**Lower Gastrointestinal Bleeding.** The first goal in evaluating and treating a patient with gastrointestinal hemorrhage is adequate resuscitation. The principles of ensuring a patent airway, supporting ventilation, and optimizing hemodynamic parameters apply, and coagulopathy and/or thrombocytopenia should be corrected. The second goal is to identify the source of hemorrhage. Because the most common source of gastrointestinal hemorrhage is esophageal, gastric, or duodenal, nasogastric aspiration should always be performed; return of bile suggests that the source of bleeding is distal to the ligament of Treitz. If aspiration reveals blood or non bile secretions, or if symptoms suggest an upper intestinal source, esophagogastroduodenoscopy is performed. Anoscopy and/or limited proctoscopy can identify hemorrhoidal bleeding. A technetium-99 (99mTc)-tagged red blood cell (RBC) scan is extremely sensitive and is able to detect as little as 0.1 mL/h of bleeding; however, localization is imprecise. If the 99mTc-tagged RBC scan is positive, angiography can then be both diagnostic and potentially therapeutic. If the patient is hemodynamically stable, a rapid bowel preparation (over 4–6 hours) can be performed to allow colonoscopy. Colonoscopy may identify the cause of the bleeding, and cautery or injection of epinephrine into the bleeding site may be used to control hemorrhage. Colectomy may be required if bleeding persists despite these interventions. Intraoperative colonoscopy and/or enteroscopy may assist in localizing bleeding. If colectomy is required, a segmental resection is preferred if the bleeding source can be localized. “Blind” subtotal colectomy may very rarely be required in a patient who is hemodynamically unstable with ongoing colonic hemorrhage of an unknown source. In this setting, just prior to proceeding with a “blind” subtotal colectomy, it is crucial to irrigate the rectosigmoid and re-examine the mucosa of the anal canal and rectum by anoscopy and proctoscopy to ensure the source of ongoing bleeding is not distal to the planned resection margin (Fig. 29-7).  

Occult blood loss from the gastrointestinal tract may manifest as iron-deficiency anemia or may be detected with FOBT. Because colon neoplasms bleed intermittently and rarely present with rapid hemorrhage, the presence of occult fecal blood should always prompt a colonoscopy. Unexplained iron-deficiency anemia is also an indication for colonoscopy.  

Hematochezia is commonly caused by hemorrhoids or a fissure. Sharp, knife-like pain and bright red rectal bleeding with bowel movements suggest the diagnosis of fissure. Painless, bright red rectal bleeding with bowel movements is often secondary to a friable internal hemorrhoid that is easily detected by anoscopy. In the absence of a painful, obvious fissure, any patient with rectal bleeding should undergo a careful digital rectal examination, anoscopy, and proctosigmoidoscopy. Failure to diagnose a source in the distal anorectum should prompt colonoscopy.  

**Constipation and Obstructed Defecation.** Constipation is an extremely common complaint, affecting more than 4 million people in the United States. Despite the prevalence of this problem, there is lack of agreement about an appropriate definition of constipation. Patients may describe infrequent bowel
movements, hard stools, or excessive straining. A careful history of these symptoms often clarifies the nature of the problem. Constipation has many causes. Underlying metabolic, pharmacologic, endocrine, psychological, and neurologic causes often contribute to the problem. A stricture or mass lesion should be excluded by colonoscopy, barium enema, or CT colonography. After these causes have been excluded, evaluation focuses on differentiating slow-transit constipation from outlet obstruction. Transit studies, in which radiopaque markers are swallowed and then followed radiographically, are useful for diagnosing slow-transit constipation. Anorectal manometry and EMG can detect nonrelaxation of the puborectalis, which contributes to outlet obstruction. The absence of an anorectal inhibitory reflex suggests Hirschsprung’s disease and may prompt a rectal mucosal biopsy. Defecography can identify rectal prolapse, intussusception, rectoceles, or enteroceles.

Medical management is the mainstay of therapy for constipation and includes fiber, increased fluid intake, and laxatives. Outlet obstruction from nonrelaxation of the puborectalis often responds to biofeedback. Surgery to correct rectoceles and rectal prolapse has a variable effect on symptoms of constipation but can be successful in selected patients. Subtotal colectomy is considered only for patients with severe slow-transit constipation (colonic inertia) refractory to maximal medical interventions. While this operation almost always increases bowel movement frequency, complaints of diarrhea, incontinence, and abdominal pain are not infrequent, and patients should be carefully selected and counseled.

Diarrhea and Irritable Bowel Syndrome. Diarrhea is also a common complaint and is usually a self-limited symptom of infectious gastroenteritis. If diarrhea is chronic or is accompanied by bleeding or abdominal pain, further investigation is warranted. Bloody diarrhea and pain are characteristic of colitis; etiology can be an infection (invasive E. coli, Shigella, Salmonella, Campylobacter, Entamoeba histolytica, or C. difficile), inflammatory bowel disease (ulcerative colitis or Crohn’s colitis), or ischemia. Stool wet-mount and culture can often diagnose infection. Sigmoidoscopy or colonoscopy can be helpful in diagnosing inflammatory bowel disease or ischemia. However, if the patient has abdominal tenderness, particularly with peritoneal signs, or any other evidence of perforation, endoscopy is contraindicated.

Chronic diarrhea may present a more difficult diagnostic dilemma. Chronic ulcerative colitis, Crohn’s colitis, infection, malabsorption, and short gut syndrome can cause chronic

Figure 29-7. Algorithm for treatment of colorectal hemorrhage. NG = nasogastric; $^{99m}$Tc = technetium-99; RBC = red blood cell. (Reproduced with permission of Taylor & Francis, LLC from Gordon PH, Nivatvongs S, eds. Principles and Practice of Surgery for the Colon, Rectum, and Anus. 2nd ed. New York: Marcel Dekker, Inc.; 1999-1279. Permission conveyed through Copyright Clearance Center, Inc.)
diarrhea. Rarely, carcinoid syndrome and islet cell tumors (vasoactive intestinal peptide–secreting tumor [VIPoma], somatostatinoma, gastrinoma) present with this symptom. Large villous lesions may cause secretory diarrhea. Collagenous colitis can cause diarrhea without any obvious mucosal abnormality. Along with stool cultures, tests for malabsorption, and metabolic investigations, colonoscopy can be invaluable in differentiating these causes. Biopsies should be taken even if the colonic mucosa appears grossly normal.

Irritable bowel syndrome is a particularly troubling constellation of symptoms consisting of crampy abdominal pain, bloating, constipation, and urgent diarrhea. Workup reveals no underlying anatomic or physiologic abnormality. Once other disorders have been excluded, dietary restrictions and avoidance of caffeine, alcohol, and tobacco may help to alleviate symptoms. Antispasmodics and bulking agents may be helpful.

Incontinence. The incidence of fecal incontinence has been estimated to occur in 10 to 13 individuals per 1000 people older than age 65 years. Incontinence ranges in severity from occasional leakage of gas and liquid stool to daily loss of solid stool. The underlying cause of incontinence is often multifactorial, and diarrhea is often contributory. In general, causes of incontinence can be classified as neurogenic or anatomic. Neurogenic causes include diseases of the central nervous system and spinal cord along with pudendal nerve injury. Anatomic causes include congenital abnormalities, procidentia (rectal prolapse), overflow incontinence secondary to impaction or an obstructing neoplasm, and trauma. The most common traumatic cause of incontinence is injury to the anal sphincter during vaginal delivery. Other causes include anorectal surgery, impalement, and pelvic fracture.

After a thorough medical evaluation to detect underlying conditions that might contribute to incontinence, evaluation focuses on assessment of the anal sphincter and pudendal nerves. Pudendal nerve terminal motor latency testing may detect neuropathy. Anal manometry can detect low resting and squeeze pressures. Physical examination and defecography can detect rectal prolapse. Endoanal ultrasound is invaluable in diagnosing sphincter defects (Fig. 29-8).

Therapy depends on the underlying abnormality. Diarrhea should be treated medically (fiber, antidiarrheal agents). Even in the absence of frank diarrhea, the addition of dietary fiber may improve continence. Some patients may respond to biofeedback. Many patients with a sphincter defect are candidates for an overlapping sphincteroplasty. Innovative technologies such as sacral nerve stimulation and the artificial bowel sphincter are proving useful in patients who fail other interventions. The delivery of radiofrequency energy to the anal canal (the Secca procedure) appears to be safe and effective in early studies. Injectable bulking agents are also gaining popularity. Physical examination and defecography can detect rectal prolapse. Endoanal ultrasound is invaluable in diagnosing sphincter defects (Fig. 29-8).

Resections

The mesenteric clearance technique dictates the extent of colonic resection and is determined by the nature of the primary pathology (malignant or benign), the intent of the resection (curative or palliative), the precise location(s) of the primary pathology, and the condition of the mesentery (thin and soft or thick and indurated). In general, a proximal mesenteric ligation will eliminate the blood supply to a greater length of colon and require a more extensive “colectomy.” Curative resection of a colorectal cancer is usually best accomplished by performing a proximal mesenteric vessel ligation and radical mesenteric clearance of the lymphatic drainage basin of the tumor site (Fig. 29-9). Resection of a benign process does not require wide mesenteric clearance.

Emergency Resection. Emergency resection may be required because of obstruction, perforation, or hemorrhage. In this setting, the bowel is almost always unprepared and the patient may
be unstable. The surgical principles described earlier apply, and an attempt should be made to resect the involved segment along with its lymphovascular supply. If the resection involves the right colon or proximal transverse colon (right or extended right colectomy), a primary ileocolonic anastomosis can usually be performed safely as long as the remaining bowel appears healthy and the patient is stable. For left-sided tumors, the traditional approach has involved resection of the involved bowel and end colostomy, with or without a mucus fistula. However, there is an increasing body of data to suggest that a primary anastomosis without a bowel preparation or with an on-table lavage, with or without a diverting ileostomy, may be equally safe in this setting. If the proximal colon appears unhealthy (vascular compromise, serosal tears, perforation), a subtotal colectomy can

be performed with a small bowel to rectosigmoid anastomosis. Resection and diversion (ileostomy or colostomy) remain safe and appropriate if the bowel appears compromised or if the patient is unstable, malnourished, or immunosuppressed.

**Minimally Invasive Techniques of Resection.** With advances in minimally invasive technology, many procedures that previously have required laparotomy can now be performed laparoscopically, with hand-assisted laparoscopy (HAL), or robotically. Potential advantages of minimally invasive surgery include improved cosmetic result, decreased postoperative pain, and earlier return of bowel function. Moreover, some experimental data suggest that minimally invasive operations have less immunosuppressive impact on the patient and thus might improve postoperative outcome and even long-term survival. To date, most studies have demonstrated equivalence between laparoscopic, HAL, and open resection in terms of extent of resection. Return of bowel function and length of hospital stay are highly variable. Long-term outcome has yet to be determined; however, short-term quality of life appears to be improved by laparoscopy. The most recent advances in minimally invasive surgery involve use of robotics and telemanipulation in which the surgeon operates from a console remote from the patient. These procedures have been rapidly gaining in popularity, especially for pelvic and rectal resections. Early studies suggest equivalence between robotic resections and laparoscopic/HAL resections.

In addition, some proponents have suggested that robotic procedures may be easier to learn (a shorter “learning curve”) and that robotic surgery may be ergonomically better for the operating surgeon. Nevertheless, long-term superiority, or even equivalence, has yet to be demonstrated, and these advanced technologies are likely to be associated with significant cost.

**Colectomy.** A variety of terms are used to describe different types of colectomy (Fig. 29-10).

**Ileocolic Resection.** An ileocolic resection describes a limited resection of the terminal ileum, cecum, and appendix. It is used to remove disease involving these segments of the intestine (e.g., ileocecal Crohn’s disease) and benign lesions or incurable cancers arising in the terminal ileum, cecum, and, occasionally, the appendix. If curable malignancy is suspected, more radical resections, such as a right hemicolectomy, are generally indicated. The ileocolic vessels are ligated and divided. A variable length of small intestine may be resected depending on the disease process. A primary anastomosis is created between the distal small bowel and the ascending colon. It is technically difficult to perform an anastomosis at or just proximal to the ileocecal valve; therefore, if the most distal ileum needs to be resected, the cecum is generally also removed.

**Right Colectomy.** A right colectomy is used to remove lesions or disease in the right colon and is oncologically the most appropriate operation for curative intent resection of proximal colon carcinoma. The ileocolic vessels, right colic vessels, and right branches of the middle colic vessels are ligated and divided. Approximately 10 cm of terminal ileum are usually included in the resection. A primary ileal-transverse colon anastomosis is almost always possible.

**Extended Right Colectomy.** An extended right colectomy may be used for curative intent resection of lesions located at the hepatic flexure or proximal transverse colon. A standard right colectomy is extended to include ligation of the middle colic vessels at their base. The right colon and proximal transverse colon are resected, and a primary anastomosis is created between the distal ileum and distal transverse colon. Such an anastomosis relies on the marginal artery of Drummond. If the blood supply to the distal transverse colon is questionable, the resection is extended distally beyond the splenic flexure to well-perfused descending colon where the ileocolic anastomosis can be performed safely.

**Transverse Colectomy.** Lesions in the mid and distal transverse colon may be resected by ligating the middle colic vessels and resecting the transverse colon, followed by a colocolonic anastomosis. However, an extended right colectomy with an anastomosis between the terminal ileum and descending colon may be a safer anastomosis with an equivalent functional result.

**Left Colectomy.** For lesions or disease states confined to the distal transverse colon, splenic flexure, or descending colon, a left colectomy is performed. The left branches of the middle colic vessels, the left colic vessels, and the first branches of the sigmoid vessels are ligated. A colocolonic anastomosis can usually be performed.

**Extended Left Colectomy.** An extended left colectomy is an option for removing lesions in the distal transverse colon. In this operation, the left colectomy is extended proximally to include the right branches of the middle colic vessels.

**Sigmoid Colectomy.** Lesions in the sigmoid colon require ligation and division of the sigmoid branches of the inferior mesenteric artery. In general, the entire sigmoid colon should be
resected to the level of the peritoneal reflection and an anastomosis created between the descending colon and upper rectum. Full mobilization of the splenic flexure is often required to create a tension-free anastomosis.

**Total and Subtotal Colectomy.** Total or subtotal colectomy is occasionally required for patients with fulminant colitis, attenuated FAP, or synchronous colon carcinomas. In this procedure, the ileocolic vessels, right colic vessels, middle colic vessels, and left colic vessels are ligated and divided. The superior rectal vessels are preserved. If it is desired to preserve the sigmoid, the distal sigmoid vessels are left intact, and an anastomosis is created between the ileum and distal sigmoid colon (subtotal colectomy with ileosigmoid anastomosis). If the sigmoid is to be resected, the sigmoidal vessels are ligated and divided, and the ileum is anastomosed to the upper rectum (total abdominal colectomy with ileorectal anastomosis). If an anastomosis is contraindicated, an end ileostomy is created, and the remaining sigmoid or rectum is managed either as a mucus fistula or a Hartmann’s pouch.

**Proctocolectomy**

**Total Proctocolectomy.** In this procedure, the entire colon, rectum, and anus are removed and the ileum is brought to the skin as a Brooke ileostomy.

**Restorative Proctocolectomy (Ileal Pouch–Anal Anastomosis).** The entire colon and rectum are resected, but the anal sphincter muscles and a variable portion of the distal anal canal are preserved. Bowel continuity is restored by anastomosis of an ileal reservoir to the anal canal. The original technique included a transanal mucosectomy and hand-sewn ileoanal anastomosis. Proponents of this technique argue that mucosectomy guarantees removal of all of the diseased mucosa, including the anal transition zone, and therefore decreases the risk of ongoing disease, dysplasia, and carcinoma. Opponents cite the increased risk of incontinence after mucosectomy and argue that even meticulous technique invariably leaves behind mucosal “islands” that are subsequently hidden under the anastomosis. Moreover, the “double-staple” technique using the circular stapling devices is considerably simpler than mucosectomy and a hand-sewn anastomosis and may be associated with a better functional outcome (Fig. 29-11). Regardless of the anastomatic technique, many surgeons recommend that patients undergo annual surveillance of the anastomosis and/or anal transition zone by digital rectal exam and anoscopy or proctoscopy.

The neorectum is made by anastomosis of the terminal ileum aligned in a “J,” “S,” or “W” configuration. Because functional outcomes are similar and because the J-pouch is the simplest to construct, it has become the most used configuration. With increasing experience in laparoscopic and robotic colectomy, some centers have begun performing total proctocolectomy with ileal pouch–anal reconstruction using minimally invasive surgical techniques.

Most surgeons perform a proximal ileostomy to divert succus from the newly created pouch in an attempt to minimize the consequences of leak and sepsis, especially in patients who are malnourished or immunosuppressed. The ileostomy is then closed 6 to 12 weeks later, after a contrast study confirms the integrity of the pouch. In low-risk patients, however, there are reports of successful creation of an ileoanal pouch without a diverting stoma.

**Anterior Resection.** Anterior resection is the general term used to describe resection of the rectum from an abdominal approach to the pelvis with no need for a perineal, sacral, or other incision. Three types of anterior resection have been described.

**High Anterior Resection.** A high anterior resection is the term used to describe resection of the distal sigmoid colon and upper rectum and is the appropriate operation for benign lesions and disease at the rectosigmoid junction such as diverticulitis. The upper rectum is mobilized, but the pelvic peritoneum is not divided and the rectum is not mobilized fully from the concavity of the sacrum. The inferior mesenteric artery is ligated at its base, and the inferior mesenteric vein, which follows a different course than the artery, is ligated separately. A primary anastomosis (usually end-to-end) between the colon and rectal stump with a short cuff of peritoneum surrounding its anterior two thirds generally can be performed.

**Low Anterior Resection.** A low anterior resection is used to remove lesions in the upper and mid rectum. The rectosigmoid is mobilized, the pelvic peritoneum is opened, and the inferior mesenteric artery is ligated and divided either at its origin from the aorta or just distal to the takeoff of the left colic artery. The rectum is mobilized from the sacrum by sharp dissection under direct view within the endopelvic fascial plane. The dissection may be performed distally to the anorectal ring, extending posteriorly through the rectosacral fascia to the coccyx and
Because the risk of an anastomotic leak and subsequent sepsis is higher when an anastomosis is created in the distal rectum or anal canal, creation of a temporary ileostomy should be considered in this setting.

Although an anastomosis may be technically feasible very low in the rectum or anal canal, it is important to note that postoperative function may be poor. Because the descending colon lacks the distensibility of the rectum, the reservoir function may be compromised. Pelvic radiation, prior anorectal surgery, and obstetrical trauma may cause unsuspected sphincter damage. Finally, a very low anastomosis may involve and compromise the upper sphincter. Creation of a colon J-pouch or transverse coloplasty may improve function, but few long-term studies have addressed this issue. 

A history of sphincter damage or any degree of incontinence is a relative contraindication for a coloanal anastomosis.

Hartmann’s Procedure and Mucus Fistula. Hartmann’s procedure refers to a colon or rectal resection without an anastomosis in which a colostomy or ileostomy is created and the distal colon or rectum is left as a blind pouch. The term is typically used when the left or sigmoid colon is resected and the closed off rectum is left in the pelvis. If the distal colon is long enough to reach the abdominal wall, a mucus fistula can be created by opening the defunctioned bowel and suturing the open lumen to the skin.

Abdominoperineal Resection. An abdominoperineal resection (APR) involves removal of the entire rectum, anal canal, and anus with construction of a permanent colostomy from the descending or sigmoid colon. The abdominal-pelvic portion of this operation proceeds in the same fashion as described for an extended low anterior resection. The perineal dissection can be performed with the patient in lithotomy position (often by a second surgeon) or in the prone position after closure of the abdomen and creation of the colostomy. For cancer, the perineal dissection is designed to excise the anal canal with a wide circumferential margin including a cylindrical cuff of the levator muscle. Primary wound closure is usually successful, but a large perineal defect, especially if preoperative radiation has been used, may require a vascularized flap closure in some patients. For benign disease, proctectomy may be performed using an intersphincteric dissection between the internal and external sphincters. This approach minimizes the perineal wound, making it easier to close because the levator muscle remains intact.

Anastomoses

Anastomoses may be created between two segments of bowel in a multitude of ways. The geometry of the anastomosis may be end-to-end, end-to-side, side-to-end, or side-to-side. The anastomotic technique may be hand-sewn or stapled (Fig. 29-13). The submucosal layer of the intestine provides the strength of the bowel wall and must be incorporated in the anastomosis to assure healing. The choice of anastomosis depends on the operative anatomy and surgeon preference. Although many surgeons advocate one method over another, none has been proven to be superior. Accurate approximation of two well-vascularized, healthy limbs of bowel without tension in a normotensive, well-nourished patient almost always results in a good outcome. Anastomoses at highest risk of leak or stricture are those that are in the distal rectal or anal canal, involve irradiated or diseased...
intestine including perforation with peritoneal soilage, or are performed in malnourished, immunosuppressed, or ill patients. 

Anastomotic Configuration 

End-to-End. An end-to-end anastomosis can be performed when two segments of bowel are roughly the same caliber. This technique is most often employed in rectal resections, but may be used for colocolostomy or small bowel anastomoses.

End-to-Side. An end-to-side configuration is useful when one limb of bowel is larger than the other. This most commonly occurs in the setting of chronic obstruction.

Side-to-End. A side-to-end anastomosis is used when the proximal bowel is of smaller caliber than the distal bowel. Ileorectal anastomoses commonly make use of this configuration. A side-to-end anastomosis may have a less tenuous blood supply than an end-to-end anastomosis.

Side-to-Side. A side-to-side anastomosis allows a large, well-vascularized connection to be created on the antimesenteric side of two segments of intestine. This technique is commonly used in ileocolic and small bowel anastomoses.

Anastomotic Technique 

Hand-Sutured Technique. Any of the configurations described earlier may be created using a hand-sutured or stapled technique. Hand-sutured anastomoses may be single layer, using either running or interrupted stitches, or double layer. A double-layer anastomosis usually consists of a continuous inner layer and an interrupted outer layer. Suture material may be either permanent 

---

or absorbable. After distal rectal or anal canal resection, a transanal, hand-sewn colon-anal anastomosis may be necessary to restore bowel continuity. This can be done in conjunction with an anal canal mucosectomy to allow the anastomosis to be created at the dentate line.

**Stapled Techniques.** Linear cutting/stapling devices are used to divide the bowel and to create side-to-side anastomoses. The anastomosis may be reinforced with interrupted sutures if desired. Circular cutting/stapling devices can create end-to-end, end-to-side, or side-to-end anastomoses. These instruments are particularly useful for creating low rectal or anal canal anastomoses where the anatomy of the pelvis makes a hand-sewn anastomosis technically difficult or impossible.

Following resection of the colorectum, a stapled end-to-end colorectal, colon-anal canal, or ileal pouch–anal canal anastomosis may be created by one of two techniques. With the *open purse-string technique*, the distal rectal stump purse-string is placed by hand, and the assembled circular stapler is inserted into the anus and guided up to the rectal purse-string. The stapler is opened, and the distal purse-string is tied. A purse-string is placed in the distal end of the proximal colon; the proximal colon is placed over the anvil and the purse-string tightened. The stapler is closed and fired (Fig. 29-14). With the alternative *double-staple technique*, the distal rectum or anal canal is closed with a transverse staple line. The circular stapler is inserted through the anus without its anvil until the cartridge effaces the transverse staple line. The stapler is opened, causing the trocar to perforate through the rectal stump adjacent to the transverse staple line. The anastomosis is then completed as described earlier (see Fig. 29-11). After firing and removing the stapler, the resulting anastomotic rings should be inspected to ensure that they are intact. A gap in an anastomotic ring suggests that the circular staple line is incomplete and the anastomosis should be reinforced with suture circumferentially, if technically feasible. A temporary proximal ileostomy may be indicated as well. Most surgeons will also *leak test* an anastomosis by instilling water or saline into the pelvis and insufflating the rectum with air via a proctoscope or alternatively instilling methylene blue or betadine into the rectum to look for extravasation.

**Ostomyes and Preoperative Stoma Planning**

Depending on the clinical situation, a stoma may be temporary or permanent. It may be end-on or a loop. However, regardless

---

**Figure 29-14.** Technique of end-to-end colorectal anastomosis using a circular stapler. A. The patient is in modified lithotomy position. B. After resection of the rectosigmoid and placement of purse-string sutures proximally and distally, the stapler is inserted into the anal canal and opened. C. Rectal purse-string suture is tied to secure the rectal stump to the rod of the stapler, and the colonic purse-string is tied to secure the colon to the anvil of the stapler. D. The stapler is closed and fired. E. The stapler is removed, leaving a circular stapled end-to-end anastomosis.
of the indication for a stoma, placement and construction are crucial for function.

The preoperative preparation of a patient who is expected to require a stoma should include a consultation with an enterostomal therapy (ET) nurse. ET nurses are specially trained and credentialed by the Wound, Ostomy and Continence Nurses Society. Preoperative planning includes counseling, education, and stoma siting. Postoperatively, the ET nurse assists with local skin care and pouching. Other considerations in stoma planning include evaluation of other medical conditions that may impact on a patient’s ability to manage a stoma (e.g., eyesight, manual dexterity).

Preoperative stoma siting is crucial for a patient’s postoperative function and quality of life. A poorly placed stoma can result in leakage and skin breakdown. Ideally, a stoma should be placed in a location that the patient can easily see and manipulate, within the rectus muscle, and below the belt line (see Fig. 29-15). Because the abdominal landmarks in a supine, anesthetized patient may be dramatically different from those in an awake, standing, or sitting patient, the stoma site should always be marked with a tattoo, skin scratch, or permanent marker preoperatively, if possible. In an emergency operation where the stoma site has not been marked, an attempt should be made to place a stoma within the rectus muscle and away from both the costal margin and iliac crest. In emergencies, placement high on the abdominal wall is preferred to a low-lying site.

For all stomas, a circular skin incision is created and the subcutaneous tissue dissected to the level of the anterior rectus sheath. The anterior rectus sheath is incised in a cruciate fashion, the muscle fibers separated bluntly, and the posterior sheath identified and incised. Care should be taken to avoid injuring and causing bleeding from the inferior epigastric artery and vein. The size of the defect depends on the size of the bowel used to create the stoma, but should be as small as possible without compromising the intestinal blood supply (usually the width of two to three fingers). The bowel is then brought through the defect and secured with sutures. The abdominal incision is usually closed and dressed prior to maturing the stoma to avoid contaminating the wound. In order to make appliance use easier, a protruding nipple is fashioned by everting the bowel. Three or four interrupted absorbable sutures are placed through the edge of the bowel, then through the serosa, approximately 2 cm proximal to the edge, and then through the dermis (Brooke technique). After the stoma is everted, the mucocutaneous junction is sutured circumferentially with interrupted absorbable suture (Fig. 29-16).

**Ileostomy**

*Temporary Ileostomy.* A temporary ileostomy is often used to “protect” an anastomosis that is at risk for leakage (low in the rectum, in an irradiated field, in an immunocompromised or malnourished patient, and during some emergency operations). In this setting, the stoma is often constructed as a loop ileostomy (see Fig. 29-12). A segment of distal ileum is brought through the defect in the abdominal wall as a loop. An enterotomy is created and the stoma matured as described earlier. The loop may be secured with or without an underlying rod. A divided loop may also be created by firing a linear cutting/stapler across the distal limb of the loop flush with the skin followed by maturation of the proximal limb of the loop.

---

**Figure 29-16.** Brooke ileostomy. A. Four sutures incorporating the cut end of the ileum, the seromuscular layer at the level of the anterior rectus fascia, and the subcuticular edge of the skin are placed at 90° to each other. B. The sutures are tied to produce stomal eversion, and C simple sutures from the cut edge of the bowel to the subcuticular tissue complete the maturation of the ileostomy. *(Reproduced with permission from Bell RH, Rikkers LF, Mulholland M, eds. Digestive Tract Surgery: A Text and Atlas. Philadelphia: Lippincott Williams & Wilkins; 1996:1278.)*
This technique prevents incomplete diversion that occasionally occurs with a loop ileostomy.

The advantage of a loop or divided loop ileostomy is that subsequent closure can often be accomplished without a formal laparotomy. An elliptical incision is created around the stoma and the bowel gently dissected free of the subcutaneous tissues and fascia. A hand-sewn or stapled anastomosis can then be created and the intestine returned to the peritoneal cavity. This avoids a long laparotomy incision and generally is well tolerated. The timing of ileostomy closure should take into account anastomotic healing as well as the patient’s overall condition. A flexible endoscopy exam and a contrast enema (Gastrografin) are recommended prior to closure to ensure that the anastomosis has not leaked and is patent. A patient’s nutritional status should be optimized. In cancer patients receiving adjuvant chemotherapy, ileostomy closure should be delayed until the chemotherapy is completed.

Permanent Ileostomy. A permanent ileostomy is sometimes required after total proctocolectomy or in patients with obstruction. An end ileostomy is the preferred configuration for a permanent ileostomy because a symmetric protruding nipple can be fashioned more easily than with a loop ileostomy (see Fig. 29-16). The end of the small intestine is brought through the abdominal wall defect and matured. Stitches are often used to secure the bowel to the posterior fascia.

Complications of Ileostomy. Stoma necrosis may occur in the early postoperative period and is usually caused by skeletonizing the distal small bowel and/or creating an overly tight fascial defect. Limited mucosal necrosis above the fascia may be treated expectantly, but necrosis below the level of the fascia requires surgical revision. Stoma retraction may occur early or late and may be exacerbated by obesity. Local revision may be necessary. The creation of an ileostomy bypasses the fluid-absorbing capability of the colon, and dehydration with fluid and electrolyte abnormalities is not uncommon. Ideally, ileostomy output should be maintained at less than 1500 mL/d to avoid this problem. Bulk agents and opioids (Lomotil, Imodium, tincture of opium) are useful. The somatostatin analogue, octreotide, has been used with varying success in this setting. Skin irritation can also occur, especially if the stoma appliance fits poorly. Skin-protecting agents and custom pouches can help to solve this problem. Obstruction may occur intra-abdominally or at the site where the stoma exits the fascia. Parastomal hernia is less common after an ileostomy than after a colostomy but can cause poor appliance fitting, pain, obstruction, or strangulation. In general, symptomatic parastomal hernias should be repaired. A variety of techniques to repair these hernias have been described, including local repair (either with or without mesh), laparoscopic repair, and stoma resiting. Prolapse is a rare, late complication and is often associated with a parastomal hernia.

Colostomy. Most colostomies are created as end colostomies rather than loop colostomies (Fig. 29-17). The bulkiness of the colon makes a loop colostomy awkward for use of an appliance, and prolapse is more likely with this configuration. Most colostomies are created on the left side of the colon. An abdominal wall defect is created and the end of the colon mobilized through it. Because a protruding stoma is considerably easier to pouch, colostomies should also be matured in a Brooke fashion. The distal bowel may be brought through the abdominal wall as a mucoc fistula or left intra-abdominally as a Hartmann’s pouch. Tacking the distal end of the colon to the abdominal wall or tagging it with permanent suture can make identification of the stump easier if the colostomy is closed at a later date. Closure of an end colostomy has traditionally required a laparotomy, but increasingly minimally invasive techniques have been adopted. The stoma is dissected free of the abdominal wall and the distal bowel identified. An end-to-end anastomosis is then created.

Complications of Colostomy. Colostomy necrosis may occur in the early postoperative period and results from an impaired vascular supply (skeletonization of the distal colon or a tight fascial defect). Like ileostomy necrosis, limited suprafascial necrosis may be followed expectantly, but necrosis below the fascia requires surgery. Retraction may also occur but is less problematic with a colostomy than with an ileostomy because the stool is less irritating to the skin than succus entericus. Obstruction is unusual, but may also occur. Parastomal hernia is the most common late complication of a colostomy and requires repair if it is symptomatic. Prolapse occurs rarely, but is more common with a loop colostomy. Interestingly, it is almost always the efferent limb of the loop that prolapses. Dehydration is rare after colostomy, and skin irritation is less common than with ileostomy.

Functional Results

Function following segmental colonic resection and primary anastomosis is generally excellent. A small percentage of patients following subtotal or total colectomy and ileosigmoid or ileorectal anastomosis may experience diarrhea and bowel frequency. This is especially true if the patient is elderly, if significant length of small bowel has been resected, and if residual proctocolitis is poorly controlled. In general, the more distal the anastomosis, the greater is the risk of troublesome diarrhea and frequency. However, some patients develop significant diarrhea after right colectomy due to malabsorption of bile acids; in these cases, bile acid binding resins (e.g., cholestyramine) sometimes can be helpful.

Function following anterior resection is highly dependent on the level of anastomosis, the use of pre- or postoperative pelvic radiation, and underlying sphincter function. Following low anterior or extended low anterior resection, some surgeons
prefer to construct a short (5-cm) colon J-pouch to anastomose to the distal rectum or anal canal or, alternatively, a transverse coloplasty to increase the capacity of the neorectum. The reservoirs are thought to lessen urgency, frequency, and incontinence, but some patients have difficulty initiating defecation, and long-term superiority over a “straight” anastomosis has yet to be proven. In addition, these reservoirs can be technically difficult, especially in an obese male with a narrow pelvis.

The physical and psychological problems associated with a permanent Brooke ileostomy led to development of the continent Kock pouch ileostomy. Unfortunately, complications, especially complications related to valve slippage, are common. Despite variations of technique designed to improve the function of the continent ileostomy, most surgeons have abandoned this operation and instead perform restorative proctocolectomy with ileal pouch–anal anastomosis.

Although ileal pouch–anal reconstruction is anatomically appealing, functional outcome is far from perfect. Patients should be counseled to expect 8 to 10 bowel movements per day. Up to 50% have some degree of nocturnal incontinence. Pouchitis occurs in nearly 50% of patients who undergo the operation for chronic ulcerative colitis, and small bowel obstruction is not uncommon. Other less common complications include difficulties with pouch evacuation, pouch-anal and/or pouch-vaginal fistula, and anal stricture. Pouch failure rate averages 5% to 10%. Patients who are subsequently diagnosed with Crohn’s disease have a considerably higher pouch failure rate (approximately 50%), whereas patients with indeterminate colitis have a lower pouch failure rate (15%–20%). Despite these drawbacks, the vast majority of patients are satisfied and prefer ileal pouch–anal reconstruction to permanent ileostomy.

**Pouchitis** is an inflammatory condition that affects both ileal pouches and continent ileostomy reservoirs. The incidence of pouchitis ranges from 30% to 55%. Symptoms include increased diarrhea, hematochezia, abdominal pain, fever, and malaise. Diagnosis is made endoscopically with biopsies. Differential diagnosis includes infection and undiagnosed Crohn’s disease. The etiology of pouchitis is unknown. Some believe pouchitits results from fecal stasis within the pouch, but emptying studies are not confirmatory. Antibiotics (metronidazole ± ciprofloxacin) are the mainstays of therapy, and most patients will respond rapidly to either oral preparations or enemas. Some patients develop chronic pouchitis that necessitates ongoing suppressive antibiotic therapy. Salicylate and corticosteroid enemas have also been used with some success. Reintroduction of normal flora by ingestion of *probiotics* and/or an elemental diet have been suggested as a possible treatment in refractory cases. Occasionally, pouch excision is necessary to control the symptoms of chronic pouchitis.

**Anesthesia Considerations**

**Local Anesthesia.** Many anorectal procedures can be performed with local anesthetic alone. Intravenous sedation is often provided to calm the patient. Injection of 0.5% lidocaine (short acting) and 0.25% bupivacaine (long acting) into the perianal skin, sphincter, and area around the pudendal nerves usually provides an adequate block. The addition of dilute epihprine decreases bleeding and prolongs the anesthetic effect.

**Regional Anesthesia.** Epidural, spinal, and caudal anesthetics can be used for anorectal procedures and transanal resections. In patients with severe medical comorbidity, regional anesthesia may occasionally be used for laparotomy and colectomy.

Postoperative epidural anesthesia provides excellent pain relief and improves pulmonary function.

**General Anesthesia.** General anesthesia is required for the vast majority of intra-abdominal procedures. Patients should undergo a thorough preoperative cardiovascular evaluation. In patients with significant comorbid disease, an anesthesia consultation may be appropriate.

**Positioning.** Most abdominal colectomies can be performed in the supine position. Anterior resection and APR require lithotomy positioning to facilitate the pelvic dissection and mobilization of the splenic flexure. Adequate padding should be provided for the patient’s sacrum, and care should be taken to avoid stirrup pressure on the peroneal nerves.

Anorectal procedures may be performed in lithotomy or in the prone jackknife position. Some surgeons prefer the prone jackknife position because exposure may be better, especially for anterior lesions. Distal posterior lesions can usually be accessed from either position, but more proximal posterior lesions are better accessed in the prone position.

**Operative Preliminaries**

**Bowel Preparation.** The rationale for bowel preparation is that decreasing the bacterial load in the colon and rectum will decrease the incidence of postoperative infection. *Mechanical bowel preparation* uses cathartics to rid the colon of solid stool the night before surgery. The most commonly used regimens include polyethylene glycol (PEG) solutions or magnesium citrate. PEG solutions require patients to drink a large volume of fluid and may cause bloating and nausea. Magnesium citrate solutions are generally better tolerated but are more likely to cause fluid and electrolyte abnormalities. Both are equally efficacious in bowel cleansing. Preparatory formulations have been recently introduced in tablet form in an attempt to improve tolerance. However, these methods of bowel cleansing require ingestion of 40 or more tablets with water over several hours. To date, these formulations have not been proven to be superior to the more traditional products. *Antibiotic prophylaxis* is also recommended. The addition of oral antibiotics to the preoperative mechanical bowel preparation has been thought to decrease postoperative infection by further decreasing the bacterial load of the colon. However, the regimens used (neomycin, erythromycin, or metronidazole) frequently caused gastrointestinal upset that interfered with the mechanical preparation, and many surgeons have abandoned oral antibiotic prophylaxis. Nevertheless, a recent analysis of the Surgical Care Improvement Project-1 (SCIP-1) suggests that oral antibiotics do reduce postoperative wound infection, especially if a mechanical bowel preparation is not used.

Prospective randomized trials are needed to better understand the role of oral antibiotic prophylaxis in colorectal surgery. In contrast, longstanding, convincing data support the efficacy of parenteral antibiotic prophylaxis at the time of surgery. Broad-spectrum parenteral antibiotic(s) with activity against aerobic and anaerobic enteric pathogens should be administered just prior to the skin incision and redosed as needed depending on the length of the operation. There is no proven benefit to using antibiotics postoperatively after an uncomplicated colectomy.

Despite widespread use of mechanical bowel preparation, the necessity of bowel cleansing prior to colectomy has been questioned. European surgeons in particular have advocated abandoning this practice. Arguments against mechanical...
bowel preparation include dehydration and electrolyte abnormalities that often result from bowel cleansing, as well as the risk of spillage of liquid stool left over from the "prep." Arguments in favor of mechanical bowel preparation included easier manipulation of an "empty" colon (especially in minimally invasive procedures) and avoidance of a "stool column" above an anastomosis, especially in the pelvis. Interestingly, a recent meta-analysis of 14 randomized controlled trials suggested that mechanical bowel preparation does not prevent surgical site infection and should be abandoned in clinical practice.36

Ureteral Stents. Ureteral stents may be useful for identifying the ureters intraoperatively and are placed via cystoscopy after the induction of general anesthesia and removed at the end of the operation. Stents can be invaluable during reoperative pelvic surgery or when there is significant retroperitoneal inflammation (such as complicated diverticulitis), as well as in obese patients. Lighted stents may be helpful in laparoscopic and robotic resections. Patients often have transient hematuria postoperatively, but major complications are rare.

Multidisciplinary Teams. Patients with complex colorectal disease often benefit from a multidisciplinary approach to their care. Patients with pelvic floor disorders (especially incontinence) often require evaluation by both a colorectal surgeon and a urologist or urogynecologist. Preoperative evaluation of cancer patients by a medical oncologist and/or radiation oncologist is crucial for planning either neoadjuvant or adjuvant therapy. Intraoperatively, complex pelvic resections often require the involvement of not only a colorectal surgeon but also a urologist, gynecologic oncologist, neurosurgeon, and/or plastic surgeon. Radiation oncologists should be involved in the operation if brachytherapy catheters are to be placed for intracavitary radiation or if intraoperative radiation therapy is planned. Rarely, psychiatric disorders may manifest as colorectal problems (especially functional disorders and chronic pain), and involvement of a psychiatrist or psychologist may be beneficial.

INFLAMMATORY BOWEL DISEASE

General Considerations

Epidemiology. Inflammatory bowel disease includes ulcerative colitis, Crohn’s disease, and indeterminate colitis. Ulcerative colitis occurs in 8 to 15 people per 100,000 in the United States and Northern Europe. The incidence is considerably lower in Asia, Africa, and South America, and among the nonwhite population in the United States. Ulcerative colitis incidence peaks during the third decade of life and again in the seventh decade of life. The incidence of Crohn’s disease is slightly lower, 1 to 5 people per 100,000. Crohn’s disease also affects Northern European and white populations disproportionately. Crohn’s disease has a similar bimodal incidence, with most cases occurring between ages 15 to 30 years and ages 55 to 60 years. In 15% of patients with inflammatory bowel disease, differentiation between ulcerative colitis and Crohn’s colitis is impossible; these patients are classified as having indeterminate colitis.

Etiology. Many different etiologies for inflammatory bowel disease have been proposed, but none are proven. The consistent geographic differences in incidence suggest an environmental factor such as diet or infection. Alcohol and oral contraceptive use have also been implicated. Smoking has been implicated in the etiology and exacerbation of Crohn’s disease in particular. Family history may play a role because 10% to 30% of patients with inflammatory bowel disease report a family member with the same disease.37,38 Other theories focus on an autoimmune mechanism and/or a defect in the intestinal immune system. While there is general agreement that interaction among the immune system, the mucosal barrier of the gut, and a variety of infectious agents is involved in the pathogenesis of inflammatory bowel disease, the mechanism(s) by which these interactions produce disease is poorly understood. Bacteria, such as Mycobacterium paratuberculosis and Listeria monocytogenes, and viruses, such as paramyxovirus and measles virus, have been suggested as etiologic agents in Crohn’s disease. A defect in the gut mucosal barrier, which increases exposure to intraluminal bacteria, toxins, or proinflammatory substances, also has been suggested. Finally, as noted earlier, an autoimmune mechanism has been postulated. Although there is no clear evidence linking an immunologic disorder to inflammatory bowel disease, the similarity of many of the extraintestinal manifestations to rheumatologic disorders has made this theory attractive. Regardless of the underlying cause of either ulcerative colitis or Crohn’s disease, both disorders are characterized by intestinal inflammation, and medical therapy is largely based on reducing inflammation.

Pathology and Differential Diagnosis. Although ulcerative colitis and Crohn’s colitis share many pathologic and clinical similarities, these conditions may be differentiated in 85% of patients. Ulcerative colitis is a mucosal process in which the colonic mucosa and submucosa are infiltrated with inflammatory cells. The mucosa may be atrophic, and crypt abscesses are common. Endoscopically, the mucosa is frequently friable and may possess multiple inflammatory pseudopolyps. In longstanding ulcerative colitis, the colon may be foreshortened and the mucosa replaced by scar. In quiescent ulcerative colitis, the colonic mucosa may appear normal both endoscopically and microscopically. Ulcerative colitis may affect the rectum (proctitis), rectum and sigmoid colon (proctosigmoiditis), rectum and left colon (left-sided colitis), or the rectum and entire colon (pancolitis). Ulcerative colitis does not involve the small intestine, but the terminal ileum may demonstrate inflammatory changes (“backwash ileitis”). A key feature of ulcerative colitis is the continuous involvement of the rectum and colon; rectal sparing or skip lesions suggest a diagnosis of Crohn’s disease. Symptoms are related to the degree of mucosal inflammation and the extent of colitis. Patients typically complain of bloody diarrhea and crampy abdominal pain. Proctitis may produce tenesmus. Severe abdominal pain and fever raise the concern of fulminant colitis or toxic megacolon. Physical findings are nonspecific and range from minimal abdominal tenderness and distention to frank peritonitis. In the nonemergent setting, the diagnosis is typically made by colonoscopy and mucosal biopsy.

In contrast to ulcerative colitis, Crohn’s disease is a transmural inflammatory process that can affect any part of the gastrointestinal tract from mouth to anus. Mucosal ulcerations, an inflammatory cell infiltrate, and noncaseating granulomas are characteristic pathologic findings. Chronic inflammation may ultimately result in fibrosis, strictures, and fistulas in either the colon or small intestine. The endoscopic appearance of Crohn’s colitis is characterized by deep serpiginous ulcers and a “cobblestone” appearance. Skip lesions and rectal sparing are common. Symptoms of Crohn’s disease depend on the severity of inflammation and/or fibrosis and the location of inflammation in the gastrointestinal tract. Acute inflammation may
produce diarrhea, crampy abdominal pain, and fever. Strictures may produce symptoms of obstruction. Weight loss is common, both because of obstruction and from protein loss. Perianal Crohn’s disease may present with pain, swelling, and drainage from fistulas or abscesses. Physical findings are also related to the site and severity of disease.

In 15% of patients with colitis from inflammatory bowel disease, differentiation of ulcerative colitis from Crohn’s colitis is impossible either grossly or microscopically (indeterminate colitis). These patients typically present with symptoms similar to ulcerative colitis. Endoscopic and pathologic findings usually include features common to both diseases. Increasingly, serologic markers have been employed to differentiate ulcerative colitis from Crohn’s disease. The anti-Saccharomyces cerevisiae antibody (ASC) and perinuclear anticytoplasmic antibody (pANCA) may be useful in differentiating these two processes but require prospective study.40

Further differential diagnoses include infectious colitides, especially Campylobacter jejuni, Entamoeba histolytica, C. difficile, Neisseria gonorrhoeae, Salmonella, and Shigella species.

Extraintestinal Manifestations. The liver is a common site of extracolonic in inflammatory bowel disease. Fatty infiltration of the liver is present in 40% to 50% of patients, and cirrhosis is found in 2% to 5%. Fatty infiltration may be reversed by medical or surgical treatment of colonic disease, but cirrhosis is irreversible. Primary sclerosing cholangitis is a progressive disease characterized by intra- and extrapathic bile duct strictures. Forty percent to 60% of patients with primary sclerosing cholangitis have ulcerative colitis. Colectomy will not reverse this disease, and the only effective therapy is liver transplantation.40 Pericholangitis is also associated with inflammatory bowel disease and may be diagnosed with a liver biopsy. Bile duct carcinoma is a rare complication of long-standing inflammatory bowel disease. Patients who develop bile duct carcinoma in the presence of inflammatory bowel disease are, on average, 20 years younger than other patients with bile duct carcinoma.

Arthritis also is a common extracolonic manifestation of inflammatory bowel disease, and the incidence is 20 times greater than in the general population. Arthritis usually improves with treatment of the colonic disease. Sacroiliitis and ankylosing spondylitis are associated with inflammatory bowel disease, although the relationship is poorly understood. Medical and surgical treatment of the colonic disease does not impact symptoms.

Erythema nodosum is seen in 5% to 15% of patients with inflammatory bowel disease and usually coincides with clinical disease activity. Women are affected three to four times more frequently than men. The characteristic lesions are raised, red, and predominantly on the lower legs. Pyoderma gangrenosum is an uncommon but serious condition that occurs almost exclusively in patients with inflammatory bowel disease. The lesion begins as an erythematous plaque, papule, or bleb, usually located on the pretribial region of the leg and occasionally near a stoma. The lesions progress and ulcerate, leading to a painful, necrotic wound. Pyoderma gangrenosum may respond to resection of the affected bowel in some patients. In others, this disorder is unaffected by treatment of the underlying bowel disease.

Up to 10% of patients with inflammatory bowel disease will develop ocular lesions. These include uveitis, iritis, episcleritis, and conjunctivitis. They usually develop during an acute exacerbation of the inflammatory bowel disease. The etiology is unknown.

**Principles of Nonoperative Management.** Medical therapy for inflammatory bowel disease focuses on decreasing inflammation and alleviating symptoms, and many of the agents used are the same for both ulcerative colitis and Crohn’s disease. In general, mild to moderate flares may be treated in the outpatient setting. More severe signs and symptoms mandate hospitalization.

Pancolitis generally requires more aggressive therapy than limited disease. Because ulcerative proctitis and proctosigmoiditis are limited to the distal large intestine, topical therapy with salicylate and/or corticosteroid suppositories and enemas can be extremely effective. Systemic therapy is rarely required in these patients.

**Salicylates.** Sulfasalazine (Azulfidine), 5-acyetyl salicylic acid (5-ASA), and related compounds are first-line agents in the medical treatment of mild to moderate inflammatory bowel disease. These compounds decrease inflammation by inhibition of cyclooxygenase and 5-lipoxygenase in the gut mucosa. They require direct contact with affected mucosa for efficacy. Multiple preparations are available for administration to different sites in the small intestine and colon (sulfasalazine, mesalamine [Pentasa, Asacol, Rowasa]).

**Antibiotics.** Antibiotics are often used to decrease the intraluminal bacterial load in Crohn’s disease. Metronidazole has been reported to improve Crohn’s colitis and perianal disease, but the evidence is weak. Fluoroquinolones may also be effective in some cases. In the absence of fulminant colitis or toxic megacolon, antibiotics are not used to treat ulcerative colitis.

**Corticosteroids.** Corticosteroids (either oral or parenteral) are a key component of treatment for an acute exacerbation of either ulcerative colitis or Crohn’s disease. Corticosteroids are nonspecific inhibitors of the immune system, and 75% to 90% of patients will improve with the administration of these drugs. However, corticosteroids have a number of serious side effects, and use of these agents should be limited to the shortest course possible. In addition, corticosteroids should be used judiciously in children because of the potential adverse effect on growth. Failure to wean corticosteroids is a relative indication for surgery.

Because of the systemic effects of corticosteroids, an effort has been made to develop drugs that act locally and have limited systemic absorption. Agents such as budesonide, beclomethasone dipropionate, and tixocortol pivalate undergo rapid hepatic degradation that significantly decreases systemic toxicity. Budesonide is available as an oral preparation. Corticosteroid enemas provide effective local therapy for proctitis and proctosigmoiditis and have fewer side effects than systemic corticosteroids.

**Immunomodulating Agents.** Azathioprine and 6-mercaptopurine (6-MP) are antimetabolite drugs that interfere with nucleic acid synthesis and thus decrease proliferation of inflammatory cells. These agents are useful for treating ulcerative colitis and Crohn’s disease in patients who have failed salicylate therapy or who are dependent on, or refractory to, corticosteroids. It is important to note, however, that the onset of action of these drugs takes 6 to 12 weeks, and concomitant use of corticosteroids almost always is required.

Cyclosporine is an immunosuppressive agent that interferes with T-lymphocyte function. While cyclosporine is not routinely used to treat inflammatory bowel disease, up to 80% of patients with an acute flare of ulcerative colitis will improve with its use. However, the majority of these patients will ultimately require colectomy. Cyclosporine is also occasionally
used to treat exacerbations of Crohn’s disease, and approximately two-thirds of patients will note some improvement. Improvement is generally apparent within 2 weeks of beginning cyclosporine therapy. Long-term use of cyclosporine is limited by its significant toxicities (e.g., nephrotoxicity, hirsutism, gum hypertrophy).

Methotrexate is a folate antagonist that also has been used to treat inflammatory bowel disease. Although the efficacy of this agent is unproven, there are reports that more than 50% of patients will improve with administration of this drug.41

**Biologic Agents.** In an effort to improve treatment for steroid-refractory inflammatory bowel disease, a new class of agents has been developed based on inhibition of tumor necrosis factor alpha (TNF-α). Intravenous infusion of these agents decreases inflammation systemically. Infliximab is a monoclonal antibody directed against TNF-α and was the first biologic agent used to treat Crohn’s disease. More than 50% of patients with moderate to severe Crohn’s disease will improve with infliximab therapy.42 This agent also has been useful in treating patients with perianal Crohn’s disease. Recurrence is common, however; and many patients require infusions on a bimonthly basis. Newer anti-TNF-α agents, such as adalimumab and certolizumab pegol, also show promise in treating Crohn’s disease.43

The use of anti-TNF-α agents for the treatment of ulcerative colitis has been less well studied, but there are reports of efficacy in this setting, and adalimumab has been approved for treatment of steroid-refractory ulcerative colitis in Europe.44,45 Interestingly, anti-TNF-α therapy may also be beneficial in treating the extraintestinal manifestations of inflammatory bowel disease in some patients.40

**Nutrition.** Patients with inflammatory bowel disease are often malnourished. Abdominal pain and obstructive symptoms may decrease oral intake. Diarrhea can cause significant protein loss. Ongoing inflammation produces a catabolic physiologic state. Parenteral nutrition should be strongly considered early in the course of therapy for either Crohn’s disease or ulcerative colitis. The nutritional status of the patient also should be considered when planning operative intervention, and nutritional parameters such as serum albumin, prealbumin, and transferrin should be assessed. In extremely malnourished patients, especially those who are also being treated with corticosteroids, creation of a stoma is often safer than a primary anastomosis.

**Ulcerative Colitis**

Ulcerative colitis is a dynamic disease characterized by remissions and exacerbations. The clinical spectrum ranges from an inactive or quiescent phase to low-grade active disease to fulminating disease. The onset of ulcerative colitis may be insidious, with minimal bloody stools, or the onset can be abrupt, with severe diarrhea and bleeding, tenesmus, abdominal pain, and fever. The severity of symptoms depends on the degree and extent of inflammation. Although anemia is common, massive hemorrhage is rare. Physical findings are often nonspecific.

The diagnosis of ulcerative colitis is almost always made endoscopically. Because the rectum is invariably involved, proctoscopy may be adequate to establish the diagnosis. The earliest manifestation is mucosal edema, which results in a loss of the normal vascular pattern. In more advanced disease, characteristic findings include mucosal friability and ulceration. Pus and mucus may also be present. While mucosal biopsy is often diagnostic in the chronic phase of ulcerative colitis, biopsy in the acute phase will often reveal only nonspecific inflammation. Evaluation with colonoscopy or barium enema during an acute flare is contraindicated because of the risk of perforation.

Barium enema has been used to diagnose chronic ulcerative colitis and to determine the extent of disease. However, this modality is less sensitive than colonoscopy and may not detect early disease. In long-standing ulcerative colitis, the colon is foreshortened and lacks haustral markings (“lead pipe” colon). Because the inflammation in ulcerative colitis is purely mucosal, strictures are highly uncommon. Any stricture diagnosed in a patient with ulcerative colitis must be presumed to be malignant until proven otherwise.

**Indications for Surgery.** Indications for surgery in ulcerative colitis may be emergent or elective. Emergency surgery is required for patients with massive life-threatening hemorrhage, toxic megacolon, or fulminant colitis who fail to respond rapidly to medical therapy. Patients with signs and symptoms of fulminant colitis should be treated aggressively with bowel rest, hydration, broad-spectrum antibiotics, and parenteral corticosteroids. Colonoscopy and barium enema are contraindicated, and antidiarrheal agents should be avoided. Deterioration in clinical condition or failure to improve within 24 to 48 hours mandates surgery.

Indications for elective surgery include intractability despite maximal medical therapy and high-risk development of major complications of medical therapy such as septic necrosis of joints secondary to chronic steroid use. Elective surgery is also indicated in patients at significant risk of developing colorectal carcinoma. The risk of malignancy increases with pancolonic disease and the duration of symptoms and is approximately 2% after 10 years, 8% after 20 years, and 18% after 30 years. Unlike sporadic colorectal cancers, carcinoma developing in the context of ulcerative colitis is more likely to arise from areas of flat dysplasia and may be difficult to diagnose at an early stage. For this reason, it is recommended that patients with long-standing ulcerative colitis undergo colonoscopic surveillance with multiple (40–50), random biopsies to identify dysplasia before invasive malignancy develops. However, the adequacy of this type of screening is controversial. Recently, magnifying chromoendoscopy has been used to improve sensitivity.46,47 This technique uses topical dyes that are applied to the colonic mucosa at the time of endoscopy (Lugol’s solution, methylene blue, indigo carmine, and others). These dyes highlight contrast between normal and dysplastic epithelium, allowing more precise biopsy of suspicious areas. Surveillance is recommended annually after 8 years in patients with pancolitis, and annually after 15 years in patients with left-sided colitis. Although low-grade dysplasia was long thought to represent minimal risk, more recent studies show that invasive cancer may be present in up to 20% of patients with low-grade dysplasia. For this reason, any patient with dysplasia should be advised to undergo proctocolectomy. Controversy exists over whether prophylactic proctocolectomy should be recommended for patients who have had chronic ulcerative colitis for greater than 10 years in the absence of dysplasia. Proponents of this approach note that surveillance colonoscopy with multiple biopsies samples only a small fraction of the colonic mucosa, and dysplasia and carcinoma are often missed. Opponents cite the relatively low risk of progression to carcinoma (approximately 2.4%) if all biopsies lack dysplasia. Neither approach has been shown definitively to decrease mortality from colorectal cancer.
Operative Management

Emergent Operation. In a patient with fulminant colitis or toxic megacolon, total abdominal colectomy with end ileostomy (with or without a mucus fistula), rather than total proctocolectomy, is recommended. Although the rectum is invariably diseased, most patients improve dramatically after an abdominal colectomy, and this operation avoids a difficult and time-consuming pelvic dissection in a critically ill patient. Rarely, a loop ileostomy and decompressing colostomy may be necessary if the patient is too unstable to withstand colectomy. Definitive surgery may then be undertaken at a later date once the patient has recovered. Complex techniques, such as an ileal pouch–anal reconstruction, generally are contraindicated in the emergent setting. However, massive hemorrhage that includes bleeding from the rectum may necessitate proctectomy and creation of either a permanent ileostomy or an ileal pouch–anal anastomosis.

Elective Operation. Elective resection for ulcerative colitis usually is performed for refractory inflammation and/or the risk of malignancy (dysplasia). Because of the risk of ongoing inflammation, the risk of malignancy, and the availability of restorative proctocolectomy, most surgeons recommend operations that include resection of the rectum. Total proctocolectomy with end ileostomy has been the “gold standard” for treating patients with chronic ulcerative colitis. This operation removes the entire affected intestine and avoids the functional disturbances associated with ileal pouch–anal reconstruction. Most patients function well physically and psychologically after this operation. Total proctocolectomy with continent ileostomy (Kock’s pouch) was developed to improve function and quality of life after total proctocolectomy, but morbidity is significant, and restorative proctocolectomy is generally preferred today. Since its introduction in 1980, restorative proctocolectomy with ileal pouch–anal anastomosis has become the procedure of choice for most patients who require total proctocolectomy but wish to avoid a permanent ileostomy (see Figs. 29-11 and 29-12). Abdominal colectomy with ileorectal anastomosis may be appropriate for a patient with indeterminate colitis and rectal sparing.

Crohn’s Disease

Similar to ulcerative colitis, Crohn’s disease is characterized by exacerbations and remissions. Crohn’s disease, however, may affect any portion of the intestinal tract, from mouth to anus. Diagnosis may be made by colonoscopy or esophagogastroduodenoscopy or by barium small bowel study or enema, depending on which part of the intestine is most affected. The presence of skip lesions is key in differentiating Crohn’s colitis from ulcerative colitis, and rectal sparing occurs in approximately 40% of patients. The most common site of involvement of Crohn’s disease is the terminal ileum and cecum (ileocolic Crohn’s disease), followed by the small bowel, and then by the colon and rectum. Perianal and anal canal Crohn’s disease manifest by complex anal fistulae and/or abscesses, anal ulcers, and large skin tags may be the initial site of presentation in up to 4% of cases.

Indications for Surgery. Because Crohn’s disease can affect any part of the gastrointestinal tract, the therapeutic rationale is fundamentally different from that of ulcerative colitis. Ulcerative colitis may be cured by removal of the affected intestinal segment (the colon and rectum). In Crohn’s disease, it is impossible to remove all the at-risk intestine; therefore, surgical therapy is reserved for complications of the disease.

Crohn’s disease may present as an acute inflammatory process or as a chronic fibrotic process. During the acute inflammatory phase, patients may present with intestinal inflammation complicated by fistulae and/or intra-abdominal abscesses. Maximal medical therapy should be instituted, including anti-inflammatory medications, bowel rest, and antibiotics. Parenteral nutrition should be considered if the patient is malnourished. Most intra-abdominal abscesses can be drained percutaneously with the use of CT scan guidance. Although the majority of these patients will ultimately require surgery to remove the diseased segment of bowel, these interventions allow the patient’s condition to stabilize, nutrition to be optimized, and inflammation to decrease prior to embarking on a surgical resection. Once an operation is undertaken, fistulae generally require resection of the segment of bowel with active Crohn’s disease; the secondary sites of the fistula are often otherwise normal and do not generally require resection after division of the fistula. Simple closure of the secondary fistula site usually suffices.

Chronic fibrosis may result in strictures in any part of the gastrointestinal tract. Because the fibrotic process is gradual, free perforation proximal to the obstructing stricture is rare. Chronic strictures almost never improve with medical therapy. Optimal timing for surgery should take into account the patient’s underlying medical and nutritional status.

Strictures may be treated with resection or strictureplasty. Distal ileal strictures are sometimes amenable to colonoscopic balloon dilatation.

Once an operation is undertaken for Crohn’s disease, several principles should guide intraoperative decision making. In general, a laparotomy for Crohn’s disease should be performed through a midline incision because of the possible need for a stoma. Laparoscopy is also increasingly used in this setting. Because many patients with Crohn’s disease often will require multiple operations, the length of bowel removed should be minimized. Bowel should be resected to an area with grossly normal margins; frozen sections are not necessary. Finally, a primary anastomosis may be created safely if the patient is medically stable, nutritionally replete, and taking few immunosuppressive medications. Creation of a stoma should be strongly considered in any patient who is hemodynamically unstable, septic, malnourished, or receiving high-dose immunosuppressive therapy and among patients with extensive intra-abdominal contamination.

Ileocolic and Small Bowel Crohn’s Disease. The terminal ileum and cecum are involved in Crohn’s disease in up to 41% of patients; the small intestine is involved in up to 35% of patients. The most common indications for surgery are internal fistula or abscess (30%–38% of patients) and obstruction (35%–37% of patients). Psas abscess may result from ileocolic Crohn’s disease. Sepsis should be controlled with percutaneous drainage of abscess(es) and antibiotics, if possible. Parenteral nutrition may be necessary in patients with chronic obstruction. The extent of resection depends on the amount of involved intestine. Short segments of inflamed small intestine and right colon should be resected and a primary anastomosis created if the patient is stable, nutrition is adequate, and immunosuppression is minimal. Isolated chronic strictures should also be resected. In patients with multiple fibrotic strictures that would require extensive small bowel resection, strictureplasty is a safe and effective alternative to resection. Short strictures are amenable to a transverse strictureplasty, while longer strictures may be treated with a side-to-side small bowel anastomosis (Fig. 29-18).
Risk of recurrence after resection for ileocolic and small bowel Crohn’s disease is high. More than 50% of patients will experience a recurrence within 10 years, and the majority of these will require a second operation.

**Crohn’s Colitis.** Crohn’s disease of the large intestine may present as *fulminant colitis* or *toxic megacolon*. In this setting, treatment is identical to treatment of fulminant colitis and toxic megacolon secondary to ulcerative colitis. Resuscitation and medical therapy with bowel rest, broad-spectrum antibiotics, and parenteral corticosteroids should be instituted. If the patient’s condition worsens or fails to rapidly improve, total abdominal colectomy with end ileostomy is recommended. An elective proctectomy may be required if the patient has refractory Crohn’s proctitis. Alternatively, if the rectum is spared, an ileorectal anastomosis may be appropriate once the patient has recovered.

Other indications for surgery in chronic Crohn’s colitis are intractability, complications of medical therapy, and risk of or development of malignancy. Unlike ulcerative colitis, Crohn’s colitis may be segmental, and rectal sparing is often observed. A segmental colectomy may be appropriate if the remaining colon and/or rectum appear normal. An isolated colonic stricture may also be treated by segmental colectomy. Although it was long thought that Crohn’s disease did not increase the risk of

---

**Figure 29-18.** Alternative stricturoplasty techniques. **A.** A short stricture is opened along the antimesenteric surface of the bowel wall. **B.** The enterotomy is closed transversely. **C.** A long stricture is opened along the antimesenteric surface of the bowel wall. **D.** The bowel is folded into an inverted “U.” **E.** A side-to-side anastomosis is made. colorectal carcinoma, it is now recognized that Crohn’s colitis (especially pancolitis) carries nearly the same risk for cancer as ulcerative colitis. Annual surveillance colonoscopy with multiple biopsies is recommended for patients with longstanding Crohn’s colitis (>7 years in duration). As in ulcerative colitis, dysplasia is an indication for total proctocolectomy. Ileal pouch–anal reconstruction is not recommended in these patients because of the risk for development of Crohn’s disease within the pouch and the high risk of complications, such as fistula, abscess, stricture, pouch dysfunction, and pouch failure.

**Anal and Perianal Crohn’s Disease.** Anal and perianal manifestations of Crohn’s disease are very common and occur in 35% of all patients with Crohn’s disease. Isolated anal Crohn’s disease is uncommon, affecting only 3% to 4% of patients. Detection of anal Crohn’s disease, therefore, should prompt evaluation of the remainder of the gastrointestinal tract.

The most common perianal lesions in Crohn’s disease are skin tags that are minimally symptomatic. Fissures are also common. Typically, a fissure from Crohn’s disease is particularly deep or broad and perhaps better described as an anal ulcer. These fissures are often multiple and located in a lateral position rather than anterior or posterior midline as seen in an idiopathic fissure in ano. A classic-appearing fissure in ano located laterally should raise the suspicion of Crohn’s disease. Perianal abscess and fistulas are common and can be particularly challenging. Fistulas tend to be complex and often have multiple tracts (Fig. 29-19). Hemorrhoids are not more common in patients with Crohn’s disease than in the general population, although many patients tend to attribute any anal or perianal symptom to “hemorrhoids.”

Treatment of anal and perianal Crohn’s disease focuses on alleviation of symptoms. Perianal skin irritation from diarrhea often responds to medical therapy directed at small bowel or colonic disease. In general, skin tags and hemorrhoids should not be excised unless they are extremely symptomatic because of the risk of creating chronic, nonhealing wounds. Fissures may respond to local or systemic therapy; sphincterotomy is relatively contraindicated because of the risk of creating a chronic, nonhealing wound and because of the increased risk of incontinence in a patient with diarrhea from underlying colitis or small bowel disease. Anal ulcers associated with Crohn’s disease are usually not very painful unless there is an underlying abscess. Thus, in patients with significant anal pain, an examination under anesthesia is indicated to exclude an underlying abscess or fistula and to assess the rectal mucosa. In the absence of active Crohn’s proctitis, one can proceed cautiously with a partial internal sphincterotomy if the examination under anesthesia reveals a classic-appearing posterior or anterior fissure and anal stenosis.

Recurrent abscess(es) or complex anal fistulae should raise the possibility of Crohn’s disease. Treatment focuses on control of infection, delineation of complex anatomy, treatment of underlying mucosal disease, and sphincter preservation. Abscesses often can be drained locally, and mushroom catheters are useful for maintaining drainage. Endoanal ultrasound and pelvic MRI are useful for mapping complex fistulous tracts. Liberal use of setons can control many fistulas and avoid division of the sphincter. Many patients with anal Crohn’s disease function well with multiple setons left in place for years. Endoanal advancement flaps may be considered for definitive therapy if the rectal mucosa is uninvolved but will not heal due to rectal inflammation. In 10% to 15% of cases, intractable perianal sepsis requires proctectomy.

Rectovaginal fistula can be a particularly difficult problem in these patients. A rectal or vaginal mucosal advancement flap may be used if the rectal mucosa appears healthy and scarring of the rectovaginal septum is minimal. Occasionally, proctectomy is the best option for women with highly symptomatic rectovaginal fistulae. Although proximal diversion is often employed to protect complex perianal reconstruction, there is no evidence that diversion alone increases healing of anal and perianal Crohn’s disease.

Medical treatment of underlying proctitis with salicylate and/or corticosteroid enemas may be helpful; however, control of infection is the primary goal of therapy. Metronidazole has been used with some success in this setting. Anti-TNF-α agents (infliximab and adalimumab) have shown some efficacy in healing chronic fistulas secondary to Crohn’s disease. The success of these agents has led to a concerted effort to identify other immunomodulators that might prove useful. Proinflammatory cytokines such as interleukin-12 and interferon-γ are potential targets. Inhibition of immune cell migration has also been suggested as an approach. However, it is of paramount importance to drain any and all abscesses before initiating immunsuppressive therapy such as corticosteroids or anti-TNF-α monoclonal antibodies.
Indeterminate Colitis

Approximately 15% of patients with inflammatory bowel disease manifest clinical and pathologic characteristics of both ulcerative colitis and Crohn’s disease. Endoscopy, barium enema, and biopsy may be unable to differentiate ulcerative colitis from Crohn’s colitis in this setting. The indications for surgery are the same as those for ulcerative colitis: intractability, complications of medical therapy, and risk of or development of malignancy. In the setting of indeterminate colitis in a patient who prefers a sphincter-sparing operation, a total abdominal colectomy with end ileostomy may be the best initial procedure. Pathologic examination of the entire colon may then allow a more accurate diagnosis. If the diagnosis suggests ulcerative colitis, an ileal pouch–anal anastomosis procedure can be performed. If the diagnosis remains in question, the safest surgical option is completion proctectomy with end ileostomy (similar to Crohn’s colitis). Ileal pouch–anal reconstruction may also be considered with the understanding that the pouch failure rate is between 15% and 20%.

DIVERTICULAR DISEASE

Diverticular disease is a clinical term used to describe the presence of symptomatic diverticula. Diverticulosis refers to the presence of diverticula without inflammation. Diverticulitis refers to inflammation and infection associated with diverticula. The majority of colonic diverticula are false diverticula in which the mucosa and muscularis mucosa have herniated through the colonic wall. These diverticula occur between the teniae coli, at points where the main blood vessels penetrate the colonic wall (presumably creating an area of relative weakness in the colonic muscle). They are thought to be pulsion diverticula resulting from high intraluminal pressure. Diverticular bleeding can be massive but usually is self-limited. True diverticula, which comprise all layers of the bowel wall, are rare and are usually congenital in origin.

Diverticulosis is extremely common in the United States and Europe. It is estimated that half of the population older than age 50 years has colonic diverticula. The sigmoid colon is the most common site of diverticulosis (Fig. 29-20). Diverticulosis is thought to be an acquired disorder, but the etiology is poorly understood. The most accepted theory is that a lack of dietary fiber results in smaller stool volume, requiring high intraluminal pressure and high colonic wall tension for propulsion. Chronic contraction then results in muscular hypertrophy and development of the process of segmentation in which the colon acts like separate segments instead of functioning as a continuous tube. As segmentation progresses, the high pressures are directed radially toward the colon wall rather than to development of propulsive waves that move stool distally. The high radial pressures directed against the bowel wall create pulsion diverticula. A loss of tensile strength and a decrease in elasticity of the bowel wall with age have also been proposed etiologies. Although none of these theories has been proven, a high-fiber diet does appear to decrease the incidence of diverticulosis. Although diverticulosis is common, most cases are asymptomatic, and complications occur in the minority of people with this condition.

Inflammatory Complications (Diverticulitis)

Diverticulitis refers to inflammation and infection associated with a diverticulum and is estimated to occur in 10% to 25% of people with diverticulosis. Peridiverticular and pericolic infection results from a perforation (either macroscopic or microscopic) of a diverticulum, which leads to contamination, inflammation, and infection. The spectrum of disease ranges from mild, uncomplicated diverticulitis that can be treated in the outpatient setting, to free perforation and diffuse peritonitis that requires emergency laparotomy. Most patients present with left-sided abdominal pain, with or without fever, and leukocytosis. A mass may be present. Plain radiographs are useful for detecting free intra-abdominal air. CT scan is extremely useful for defining pericolic inflammation, phlegmon, or abscess. Contrast enemas and/or endoscopy are relatively contraindicated because of the risk of perforation. The differential diagnosis includes malignancy, ischemic colitis, infectious colitis, and inflammatory bowel disease.

Uncomplicated Diverticulitis. Uncomplicated diverticulitis is characterized by left lower quadrant pain and tenderness. CT findings include pericolic soft tissue stranding, colonic wall thickening, and/or phlegmon. Most patients with uncomplicated diverticulitis will respond to outpatient therapy with broad-spectrum oral antibiotics and a low-residue diet. Antibiotics should be continued for 7 to 10 days. About 10% to 20% of patients with more severe pain, tenderness, fever, and leukocytosis are treated in the hospital with parenteral antibiotics and bowel rest. Most patients improve within 48 to 72 hours. Failure to improve may suggest abscess formation. CT can be extremely useful in this setting, and many pericolic abscesses can be drained percutaneously (see below). Deterioration in a patient’s clinical condition and the development of peritonitis are indications for laparotomy.

Most patients with uncomplicated diverticulitis will recover without surgery, and 50% to 70% will have no further
episodes. It has long been believed that the risk of complications increases with recurrent disease. For this reason, elective sigmoid colectomy has often been recommended after the second episode of diverticulitis, especially if the patient has required hospitalization. Resection has often been recommended after the first episode in very young patients and is often recommended after the first episode of complicated diverticulitis. These general guidelines have been questioned in recent years, and more recent studies suggest that the risk of complications and/or need for emergent resection does not increase with recurrent disease.

Many surgeons now will not advise colectomy even after two documented episodes of diverticulitis assuming the patient is completely asymptomatic and that carcinoma has been excluded by colonoscopy. Immunosuppressed patients are generally still advised to undergo colectomy after a single episode of documented diverticulitis. Medical comorbidities should be considered when evaluating a patient for elective resection, and the risks of recurrent disease should be weighed against the risks of the operation. Because colon carcinoma may present in an identical fashion to diverticulitis (either complicated or uncomplicated), all patients must be evaluated for malignancy after resolution of the acute episode. Colonoscopy is recommended 4 to 6 weeks after recovery. Inability to exclude malignancy is another indication for resection.

In the elective setting, a sigmoid colectomy with a primary anastomosis is the procedure of choice. The resection should always be extended to the rectum distally because the risk of recurrence is high if a segment of sigmoid colon is retained. The proximal extent of the resection should include all thickened or inflamed bowel; however, resection of all diverticula is unnecessary. Increasingly, laparoscopy is being used for elective sigmoid colectomy for diverticular disease. Complicated Diverticulitis. Complicated diverticulitis includes diverticulitis with abscess, obstruction, diffuse peritonitis (free perforation), or fistulas between the colon and adjacent structures. Colovesical, colovaginal, and coloenteric fistulas are long-term sequelae of complicated diverticulitis. The Hinchey staging system is often used to describe the severity of complicated diverticulitis: Stage I includes colonic inflammation with an associated pericolic abscess; stage II includes colonic inflammation with a retroperitoneal or pelvic abscess; stage III is associated with purulent peritonitis; and stage IV is associated with fecal peritonitis. Treatment depends on the patient’s overall clinical condition and the degree of peritoneal contamination and infection. Small abscesses (<2 cm in diameter) may be treated with parenteral antibiotics. Larger abscesses are best treated with CT-guided percutaneous drainage (Fig. 29-21) and antibiotics. Many of these patients will ultimately require resection, but percutaneous drainage may allow a one-stage, elective procedure and may obviate the need for colectomy if full recovery follows the drainage.

Urgent or emergent laparotomy may be required if an abscess is inaccessible to percutaneous drainage, if the patient’s condition deteriorates or fails to improve, or if the patient presents with free intra-abdominal air or peritonitis. In almost all cases, an attempt should be made to resect the affected segment of bowel. Patients with small, localized pericolic or pelvic abscesses (Hinchey stages I and II) may be candidates for a sigmoid colectomy with a primary anastomosis (a one-stage operation). Among patients with larger abscesses, peritoneal soiling, or peritonitis, sigmoid colectomy with end colostomy and Hartmann’s pouch is the most commonly used procedure. Success also has been reported after sigmoid colectomy, primary anastomosis, with or without on-table lavage, and proximal diversion (loop ileostomy). This option may be appropriate in stable patients and offers the great advantage that the subsequent operation to restore bowel continuity is simpler than is takedown of a Hartmann’s pouch. The presence of inflammation and phlegmon may increase the risk of ureteral damage during mobilization of the sigmoid colon, and preoperative placement of ureteral catheters can be invaluable. In extremely unstable patients, or in the presence of such severe inflammation that resection would harm adjacent organs, proximal diversion and local drainage have been employed. However, this approach is generally avoided because of high morbidity and mortality.

Figure 29-21. A. Computed tomography scan demonstrating pelvic abscess from perforated diverticular disease. B. Posterolateral computed tomography–guided drainage of abdominal abscess from perforated diverticular disease. (Both images used with permission of Charles O. Finne III, MD, Minneapolis, MN.)
rates, along with the requirement for multiple operations. More recently, several studies have suggested that laparoscopic lavage and drainage without bowel resection may be safe and effective even in the presence of free perforation. Nevertheless, this approach remains controversial and will require additional prospective trials before it can be recommended under most circumstances.

Obstructive symptoms occur in approximately 67% of patients who develop acute diverticulitis, and complete obstruction occurs in 10%. Patients with incomplete obstruction often respond to fluid resuscitation, nasogastric suction, and gentle, low-volume water or Gastrografin enemas. Relief of obstruction allows full bowel preparation and elective resection. A high-volume oral bowel preparation is contraindicated in the presence of obstructive symptoms. Obstruction that does not rapidly respond to medical management mandates laparotomy. Sigmoid colectomy with end colostomy is the safest procedure to perform in this setting. However, colectomy and primary anastomosis, with or without on-table lavage (depending on extent of fecal load in the proximal colon), and proximal diversion may be appropriate if the patient is stable and the proximal and distal bowel appear healthy.

Approximately 5% of patients with complicated diverticulitis develop fistulas between the colon and an adjacent organ. Colovesical fistulas are most common, followed by colovaginal and coloenteric fistulas. Colocutaneous fistulas are a rare complication of diverticulitis. Two key points in the evaluation of fistulas are to define the anatomy of the fistula and exclude other diagnoses. Contrast enema and/or small bowel studies are extremely useful in defining the course of the fistula. CT scan can identify associated abscesses or masses. The differential diagnosis includes malignancy, Crohn’s disease, and radiation-induced fistulas. While Crohn’s disease and radiation injury may be suspected based on the patient’s medical history, colonoscopy or sigmoidoscopy usually is required to rule out malignancy. In addition, in a patient who has received radiation therapy, a fistula must be considered to be recurrent cancer until proven otherwise. Once the anatomy of the fistula has been defined and other diagnoses excluded, operative management should include resection of the affected segment of the colon involved with diverticulitis (usually with a primary anastomosis) and simple repair of the secondarily involved organ. Suspicion of carcinoma may mandate a wider, en bloc resection.

**Hemorrhage**

Bleeding from a diverticulum results from erosion of the peridiverticular arteriole and may result in massive hemorrhage. Most significant lower gastrointestinal hemorrhage occurs in elderly patients in whom both diverticulosis and angiodysplasia are common. Consequently, the exact bleeding source may be difficult to identify. Fortunately, in 80% of patients, bleeding stops spontaneously. Clinical management should focus on resuscitation and localization of the bleeding site as described for lower gastrointestinal hemorrhage. Colonoscopy may occasionally identify a bleeding diverticulum that may then be treated with epinephrine injection or cautery. Angiography may be diagnostic and therapeutic in this setting. In the rare instance in which diverticular hemorrhage persists or recurs, laparotomy and segmental colectomy may be required.

**Giant Colonic Diverticulum**

Giant colonic diverticula are extremely rare. Most occur on the antimesenteric side of the sigmoid colon. Patients may be asymptomatic or may present with vague abdominal complaints such as pain, nausea, or constipation. Plain radiographs may suggest the diagnosis. Barium enema is usually diagnostic. Complications of a giant diverticulum include perforation, obstruction, and volvulus. Resection of the involved colon and diverticulum is recommended.

**Right-Sided Diverticula**

The cecum and ascending colon infrequently are involved in diverticulosis coli. Even more uncommon is a true solitary diverticulum, which contains all layers of the bowel wall and is thought to be congenital in origin. Right-sided diverticula occur more often in younger patients than do left-sided diverticula and are more common in people of Asian descent than in other populations. Most patients with right-sided diverticula are asymptomatic. However, diverticulitis does occur occasionally. Because patients are young and present with right lower quadrant pain, they are often thought to suffer from acute appendicitis, and the diagnosis of right-sided diverticulitis is subsequently made in the operating room. If there is a single large diverticulum and minimal inflammation, a diverticulectomy may be performed, but an ileocecal resection is usually the preferred operation in this setting. Hemorrhage rarely occurs and should be treated in the same fashion as hemorrhage from a left-sided diverticulum.

**ADENOCARCINOMA AND POLYPS**

**Incidence**

Colorectal carcinoma is the most common malignancy of the gastrointestinal tract. Over 140,000 new cases are diagnosed annually in the United States, and more than 50,000 patients die of this disease each year, making colorectal cancer the third most lethal cancer in the United States.51

The incidence is similar in men and women and has remained fairly constant over the past 20 years; however, the widespread adoption of current national screening programs is gradually decreasing the incidence of this common and lethal disease. Early detection and improvements in medical and surgical care are thought to be responsible for the decreasing mortality of colorectal cancer observed in recent years.

**Epidemiology (Risk Factors)**

Identification of risk factors for development of colorectal cancer is essential to establish screening and surveillance programs in appropriately targeted populations.

**Aging.** Aging is the dominant risk factor for colorectal cancer, with incidence rising steadily after age 50 years. More than 90% of cases diagnosed are in people older than age 50 years. This is the rationale for initiating screening tests of asymptomatic patients at average risk of developing colorectal cancer at age 50 years. However, individuals of any age can develop colorectal cancer, so symptoms such as a significant change in bowel habits, rectal bleeding, melena, unexplained anemia, or weight loss require a thorough evaluation.

**Hereditary Risk Factors.** Approximately 80% of colorectal cancers occur sporadically, while 20% arise in patients with a known family history of colorectal cancer. Advances in the understanding of these familial disorders have led to interest in early diagnosis using genetic testing. Because of the medical, legal, and ethical considerations that are involved in this type
of testing, all patients should be offered genetic counseling if a familial syndrome is suspected.

**Environmental and Dietary Factors.** The observation that colorectal carcinoma occurs more commonly in populations that consume diets high in animal fat and low in fiber has led to the hypothesis that dietary factors contribute to carcinogenesis. A diet high in saturated or polyunsaturated fats increases risk of colorectal cancer, while a diet high in oleic acid (olive oil, coconut oil, fish oil) does not increase risk. Animal studies suggest that fats may be directly toxic to the colonic mucosa and thus may induce early malignant changes. In contrast, a diet high in vegetable fiber appears to be protective. A correlation between alcohol intake and incidence of colorectal carcinoma has also been suggested. Ingestion of calcium, selenium, vitamins A, C, and E, carotenoids, and plant phenols may decrease the risk of developing colorectal cancer. Obesity and sedentary lifestyle dramatically increase cancer-related mortality in a number of malignancies, including colorectal carcinoma. This knowledge is the basis for primary prevention strategies to eliminate colorectal cancer by altering diet and lifestyle.  

**Inflammatory Bowel Disease.**Patients with long-standing colitis from inflammatory bowel disease are at increased risk for the development of colorectal cancer. It is hypothesized that chronic inflammation predisposes the mucosa to malignant changes, and there is some evidence that degree of inflammation influences risk. In general, the duration and extent of colitis correlate with risk. Other factors thought to increase risk include the presence of primary sclerosing cholangitis and family history of colorectal cancer.

**Other Risk Factors.** Cigarette smoking is associated with an increased risk of colon adenomas, especially after more than 35 years of use. Patients with ureterosigmoidostomy are also at increased risk for both adenoma and carcinoma formation.  

Acromegaly, which is associated with increased levels of circulating human growth hormone and insulin-like growth factor-1, increases risk as well. Pelvic irradiation may increase the risk of developing rectal carcinoma. However, it is unclear whether this represents a direct effect of radiation damage or is instead a correlation between the development of rectal cancer and a history of another pelvic malignancy; for example among patients who develop prostate cancer and are treated with radiation, the risk of rectal cancer increases significantly.  

**Pathogenesis of Colorectal Cancer**

**Genetic Defects.** Over the past two decades, an intense research effort has focused on elucidating the genetic defects and molecular abnormalities associated with the development and progression of colorectal adenomas and carcinoma. Mutations may cause activation of oncogenes (K-ras) and/or inactivation of tumor suppressor genes (APC, deleted in colorectal carcinoma [DCC], p53). Colorectal carcinoma is thought to develop from adenomatous polyps by accumulation of these mutations in what has come to be known as the adenoma-carcinoma sequence (Fig. 29-22).

Defects in the APC gene were first described in patients with FAP. By investigating these families, characteristic mutations in the APC gene were identified. They are now known to be present in 80% of sporadic colorectal cancers as well.

The APC gene is a tumor suppressor gene. Mutations in both alleles are necessary to initiate polyp formation. The majority of mutations are premature stop codons, which result in a truncated APC protein. In FAP, the site of mutation correlates with the clinical severity of the disease. For example, mutations in either the 3’ or 5’ end of the gene result in attenuated forms of FAP (AFAP), whereas mutations in the center of the gene result in more virulent disease. Thus, knowledge of the specific mutation in a family may help guide clinical decision making.

APC inactivation alone does not result in a carcinoma. Instead, this mutation sets the stage for the accumulation of genetic damage that results in malignancy. Additional mutations may include activation or inactivation of a variety of genes.

One of the most commonly involved genes in colorectal cancer is K-ras. K-ras, a signaling molecule in the epidermal growth factor receptor (EGFR) pathway, is classified as a proto-oncogene because mutation of only one allele will perturb the cell cycle. The K-ras gene product is a G-protein involved in intracellular signal transduction. When active, K-ras binds guanosine triphosphate (GTP); hydrolysis of GTP to guanosine diphosphate (GDP) then inactivates the G-protein. Mutation of K-ras results in an inability to hydrolyze GTP, thus leaving the G-protein permanently in the active form. It is thought that this then leads to uncontrolled cell division. Other EGFR signaling molecules such as BRAF have also been implicated in colorectal cancer pathogenesis and progression, and ongoing research is focusing on elucidating their roles in this disease.

Another common mutation occurs in the MYH gene on chromosome 1p. MYH is a base excision repair gene, and biallelic deletion results in changes in other downstream molecules. Since its discovery, MYH mutations have been associated with an AFAP phenotype in addition to sporadic cancers. Unlike APC gene mutations that are expressed in an autosomal dominant pattern, the requirement for biallelic mutation in MYH results in an autosomal recessive pattern of inheritance.

The tumor suppressor gene p53 has been well characterized in a number of malignancies. The p53 protein appears...
to be crucial for initiating apoptosis in cells with irreparable genetic damage. Mutations in \( p53 \) are present in 75% of colorectal cancers.

Deletion of the tumor suppressor phosphatase and tensin homolog (\( PTEN \)) appears to be involved in a number of hamartomatous polyposis syndromes. Deletions in \( PTEN \) have been identified in juvenile polyposis, Peutz-Jeghers syndrome, Cowden’s syndrome, and \( PTEN \) hamartoma syndrome, in addition to multiple endocrine neoplasia type IIB.\(^{15} \)

**Genetic Pathways.** The mutations involved in colorectal cancer pathogenesis and progression are now recognized to accumulate via one of three major genetic pathways: the loss of heterozygosity (LOH; chromosomal instability) pathway, the microsatellite instability (MSI) pathway, and the CpG island methylation (CIMP; serrated methylated) pathway.

**The Loss of Heterozygosity Pathway.** The LOH pathway is characterized by chromosomal deletions and tumor aneuploidy. Eighty percent of colorectal carcinomas appear to arise from mutations in the LOH pathway. This pathway was first described in patients with FAP in whom mutations of the \( APC \) gene were found to be inherited.

Another example of LOH occurs in the region of chromosome 18q. This region has been found to be deleted in up to 70% of colorectal cancers. Two tumor suppressor genes, \( DCC \) and \( SMAD4 \), are located in this region, and as such, deletion of 18q may result in the loss of one or both of these genes. \( DCC \) is a tumor suppressor gene, and loss of both alleles is required for malignant degeneration. The main role of this molecule appears to be in the central nervous system, where it is involved in neural differentiation and axonal migration. This observation has led to the hypothesis that \( DCC \) may be involved in differentiation and cellular adhesion in colorectal cancer, but this theory remains unproven.\(^{16} \) \( DCC \) mutations are present in more than 70% of colorectal carcinomas and may negatively impact prognosis. \( SMAD4 \) functions in the signaling cascade of transforming growth factor beta and beta-catenin (also a downstream effector of the \( APC \) gene). Loss of either of these genes is thought to promote cancer progression.

**The Microsatellite Instability Pathway.** Many of the remaining colorectal carcinomas are thought to arise from mutations in the MSI pathway, which is characterized by errors in mismatch repair during DNA replication. These errors in mismatch repair were first described in HNPPC (Lynch’s syndrome), but are now recognized to be present in many sporadic tumors as well. A number of genes have been identified that appear to be crucial for recognizing and repairing DNA replication errors. These mismatch repair genes include \( MSH2 \), \( MLH1 \), \( PMS1 \), \( PMS2 \), and \( MSH6/GTBP \). A mutation in one of these genes predisposes a cell to mutations, which may occur in proto-oncogenes or tumor suppressor genes. Accumulation of these errors then leads to genomic instability and ultimately to carcinogenesis.

Microsatellites are regions of the genome in which short base-pair segments are repeated several times, regions that are particularly prone to replication error. Consequently, a mutation in a mismatch repair gene produces variable lengths of these repetitive sequences, a finding that has been described as MSI.

Tumors associated with MSI appear to have different biological characteristics than do tumors that result from the LOH pathway. Tumors with MSI are more likely to be in the right colon and possess diploid DNA and are associated with a better prognosis than tumors that arise from the LOH pathway that are microsatellite stable. Tumors arising from the LOH pathway tend to occur in the more distal colon, often have chromosomal aneuploidy, and are associated with a poorer prognosis.

**CpG Island Methylation Pathway.** In the recently described CIMP pathway, genes do not accumulate mutations (deletions or insertions of bases), but instead are activated or inactivated by methylation. This process has been called epigenetic alteration to differentiate it from the more traditional genetic alterations or true mutations. In normal cells, methylation is critical for regulation of gene expression. In cancer, aberrant methylation (either hyper- or hypomethylation), usually of a promoter region, results in abnormal activation or inactivation of genes. This gene silencing or, alternatively, activation results in a phenotype similar to that present with a true gene mutation. This pathway has also been called the serrated methylated pathway because of the observation that serrated polyps often harbor aberrant methylation in contrast to adenomatous polyps that are more often associated with mutations in the \( APC \) gene (LOH pathway).\(^{18} \)

Although these classifications are useful for understanding the mechanisms underlying carcinogenesis, they are not mutually exclusive. For example, a mismatch repair gene may be inactivated by methylation. Errors in mismatch repair may then allow mutations to inactivate a tumor suppressor gene. In addition, there is considerable interest in targeting molecules in each of these pathways in order to design better anticancer agents. Finally, ongoing research is focusing on the utility of molecular profiling in predicting prognosis and/or response to treatment.

**Polyps.** It is now well accepted that the majority of colorectal carcinomas evolve from adenomatous polyps; this sequence of events is the adenoma-carcinoma sequence. Polyp is a nonspecific clinical term that describes any projection from the surface of the intestinal mucosa regardless of its histologic nature. Colorectal polyps may be classified as neoplastic (tubular adenoma, villous adenoma, tubulovillous adenomas, serrated adenomas/ polyps), hyperplastic, hamartomatous (juvenile, Peutz-Jeghers, Cronkite-Canada), or inflammatory (pseudo-polyp, benign lymphoid polyp).

**Neoplastic Polyps.** Adenomatous polyps are common, occurring in up to 25% of the population older than 50 years of age in the United States. By definition, these lesions are dysplastic. The risk of malignant degeneration is related to both the size and type of polyp. Tubular adenomas are associated with malignancy in only 5% of cases, whereas villous adenomas may harbor cancer in up to 40%. Tubulovillous adenomas are at intermediate risk (22%). Invasive carcinomas are rare in polyps smaller than 1 cm; the incidence increases with size. The risk of carcinoma in a polyp larger than 2 cm is 35% to 50%. Although most neoplastic polyps do not evolve to cancer, most colorectal cancers originate as a polyp. It is this fact that forms the basis for secondary prevention strategies to eliminate colorectal cancer by targeting the neoplastic polyp for removal before malignancy develops.

Polyps may be pedunculated or sessile. Most pedunculated polyps are amenable to colonoscopic snare excision. Removal of sessile polyps is often more challenging. Special colonoscopic techniques, including saline lift, piecemeal snare excision, and endoscopic mucosal resection facilitate successful removal of many sessile polyps. For rectal sessile polyps, transanal operative excision is preferred because it produces an
intact, single pathology specimen that can be used to determine the need for further therapy. Interpretation of the precise depth of invasion of a cancer arising in a sessile polyp after piecemeal excision is often impossible. The site of sessile polypectomies should be marked by injection of India ink to guide follow-up colonoscopy sessions to ensure that the polyp has been completely removed and to facilitate identification of the involved bowel segment should operative resection be necessary. Colectomy is reserved for cases in which colonoscopic removal is impossible, such as large, flat lesions, or if a focus of invasive cancer is confirmed in the specimen.

Complications of polypectomy include perforation and bleeding. A small perforation (microperforation) in a fully prepared, stable patient may be managed with bowel rest, broad-spectrum antibiotics, and close observation. Signs of sepsis, peritonitis, or deterioration in clinical condition are indications for laparotomy. Bleeding may occur immediately after polypectomy or may be delayed. The bleeding will usually stop spontaneously, but colonoscopy may be required to resuture a bleeding stalk or cauterize the lesion. Occasionally angiography and infusion of vasopressin may be necessary. Rarely, colectomy is required.

**Hyperplastic Polyps.** Hyperplastic polyps are extremely common in the colon. These polyps are usually small (<5 mm) and show histologic characteristics of hyperplasia without any dysplasia. They are not considered premalignant, but cannot be distinguished from adenomatous polyps colonoscopically and are therefore often removed. In contrast, large hyperplastic polyps (>2 cm) may have a slight risk of malignant degeneration. Moreover, large polyps may harbor foci of adenomatous tissue and dysplasia. **Hyperplastic polyposis** is a rare disorder in which multiple large hyperplastic polyps occur in young adults. These patients are at slightly increased risk for the development of colorectal cancer.

**Serrated Polyps.** Serrated polyps are a recently recognized, histologically distinct group of neoplastic polyps. These lesions were long thought to be similar to hyperplastic polyps with minimal malignant potential. However, it has become clear that some of these polyps will develop into invasive cancers. In addition, a familial *serrated polyposis syndrome* has recently been described. Serrated polyps should be treated like adenomatous polyps.

**Hamartomatous Polyps (Juvenile Polyps).** In contrast to adenomatous and serrated polyps, hamartomatous polyps (juvenile polyps) usually are not premalignant. These lesions are the characteristic polyps of childhood but may occur at any age. Bleeding is a common symptom, and intussusception and/or obstruction may occur. Because the gross appearance of these polyps is identical to adenomatous polyps, these lesions should also be treated by polypectomy. In contrast to adenomatous polyps, these conditions are often associated with mutation in **PTEN**.

**Familial juvenile polyposis** is an autosomal dominant disorder in which patients develop hundreds of polyps in the colon and rectum. Unlike solitary juvenile polyps, these lesions may degenerate into adenomas and eventually carcinoma. Annual screening should begin between the ages of 10 and 12 years. Treatment is surgical and depends in part on the degree of rectal involvement. If the rectum is relatively spared, a total abdominal colectomy with ileorectal anastomosis may be performed with subsequent close surveillance of the retained rectum. If the rectum is carpeted with polyps, total proctocolectomy is the more appropriate operation. These patients are candidates for ileal pouch–anal reconstruction to avoid a permanent stoma.

**Peutz-Jeghers syndrome** is characterized by polyposis of the small intestine and, to a lesser extent, polyposis of the colon and rectum. Characteristic melanin spots are often noted on the buccal mucosa and lips of these patients. The polyps of Peutz-Jeghers syndrome are generally considered to be hamartomas and are not thought to be at significant risk for malignant degeneration. However, carcinoma may occasionally develop. Because the entire length of the gastrointestinal tract may be affected, surgery is reserved for symptoms such as obstruction or bleeding or for patients in whom polyps develop adenomatous features. Screening consists of a baseline colonoscopy and upper endoscopy at age 20 years, followed by annual flexible sigmoidoscopy thereafter.

**Cronkite-Canada syndrome** is a disorder in which patients develop gastrointestinal polyposis in association with alopecia, cutaneous pigmentation, and atrophy of the fingernails and toenails. Diarrhea is a prominent symptom, and vomiting, malabsorption, and protein-losing enteropathy may occur. Most patients die of this disease despite maximal medical therapy, and surgery is reserved for complications of polyposis such as obstruction.

**Cowden’s syndrome** is an autosomal dominant disorder with hamartomas of all three embryonal cell layers. Facial trichilemmomas, breast cancer, thyroid disease, and gastrointestinal polyps are typical of the syndrome. Patients should be screened for cancers. Treatment is otherwise based on symptoms.

**Inflammatory Polyps (Pseudopolyps).** Inflammatory polyps occur most commonly in the context of inflammatory bowel disease, but may also occur after amebic colitis, ischemic colitis, and schistosomal colitis. These lesions are not premalignant, but they cannot be distinguished from adenomatous polyps based on gross appearance and therefore should be removed. Microscopic examination shows islands of normal, regenerating mucosa (the polyp) surrounded by areas of mucosal loss. Polyposis may be extensive, especially in patients with severe colitis, and may mimic FAP.

**Inherited Colorectal Carcinoma**

Many of the genetic defects originally described in hereditary cancers have subsequently been found in sporadic tumors. Although the majority of colorectal cancer is sporadic, several hereditary syndromes provide paradigms for the study of this disease. Insight gained from studying inherited colorectal cancer syndromes has led to better understanding of the genetics of colorectal carcinoma.

**Familial Adenomatous Polyposis.** This rare autosomal dominant condition accounts for only about 1% of all colorectal adenocarcinomas. Nevertheless, this syndrome has provided tremendous insight into the molecular mechanisms underlying colorectal carcinogenesis. The genetic abnormality in FAP is a mutation in the **APC** gene, located on chromosome 5q. Of patients with FAP, **APC** mutation testing is positive in 75% of cases. While most patients with FAP will have a known family history of the disease, up to 25% present without other affected family members. Clinically, patients develop hundreds to thousands of adenomatous polyps shortly after puberty. The lifetime risk of colorectal cancer in FAP patients approaches 100% by age 50 years.

Flexible sigmoidoscopy of first-degree relatives of FAP patients beginning at age 10 to 15 years has been the traditional
mainstay of screening. Today, following genetic counseling, APC gene testing may be used to screen family members, providing an APC mutation has been identified. If APC testing is positive in a relative of a patient with a known APC mutation, annual flexible sigmoidoscopy beginning at age 10 to 15 years is done until polyps are identified. If APC testing is negative, the relative can be screened starting at age 50 years per average-risk guidelines. If APC testing is refused or unavailable, or if a mutation cannot be identified, annual flexible sigmoidoscopy beginning at age 10 to 15 years is performed until age 24 years. Screening flexible sigmoidoscopy is then done every 2 years until age 34 years, every 3 years until age 44 years, and then every 3 to 5 years.

AFAP patients are also at risk for the development of adenomas anywhere in the gastrointestinal tract, particularly in the duodenum. Periampullary carcinoma is a particular concern. Upper endoscopy is therefore recommended for surveillance every 1 to 3 years beginning at age 25 to 30 years.

Once the diagnosis of FAP has been made and polyps are developing, treatment is surgical. Four factors affect the choice of operation: age of the patient; presence and severity of symptoms; extent of rectal polyposis; and presence and location of cancer or desmoid tumors. Three operative procedures can be considered: total proctocolectomy with an end (Brooke) ileostomy; total abdominal colectomy with ileorectal anastomosis; and restorative proctocolectomy with ileal pouch–anal anastomosis with or without a temporary ileostomy. Most patients elect to have an ileal pouch–anal anastomosis in the absence of a distal rectal cancer, a mesenteric desmoid tumor that prevents the ileum from reaching the anus, or poor sphincter function. Mucosectomy has been advocated in patients with FAP undergoing ileal pouch–anal anastomosis because of the risk of neo-plasia in the anal transition zone, but the requirement for this procedure remains controversial. Although patient satisfaction with this procedure remains high, function may not be ideal, and up to 50% of patients experience some degree of incontinence. Total abdominal colectomy with an ileorectal anastomosis is also an option in these patients, but requires vigilant surveillance of the retained rectum for development of rectal cancer. There is increasing data suggesting that the administration of cyclo-oxygenase-2 (COX-2) inhibitors (celecoxib, sulindac) may slow or prevent the development of polyps.  

FAP may be associated with extraintestinal manifestations such as congenital hypertrophy of the retinal pigmented epithelium, desmoid tumors, epidermoid cysts, mandibular osteomas (Gardner’s syndrome), and central nervous system tumors (Turcot’s syndrome). Desmoid tumors in particular, can make surgical management difficult and are a source of major morbidity and mortality in these patients. Desmoid tumors are often hormone responsive, and growth may be inhibited in some patients with tamoxifen. COX-2 inhibitors and nonsteroidal, anti-inflammatory drugs may also be beneficial in this setting.

**Attenuated Familial Adenomatous Polyposis**. AFAP is a recognized variant of FAP. Patients present later in life with fewer polyps (usually 10–100) predominantly located in the right colon, when compared to classic FAP. Colorectal carcinoma develops in more than 50% of these patients, but occurs later (average age, 55 years). Patients are also at risk for duodenal polyposis. However, in contrast to FAP, APC gene mutations are present in only about 30% of patients with AFAP. When present, these mutations are expressed in an autosomal dominant pattern.

Mutations in MYH also result in the AFAP phenotype but are expressed in an autosomal recessive pattern. It has been suggested that MYH mutations may be responsible for AFAP in patients who do not have a detectable APC gene mutation.  

Genetic testing is often offered to patients with suspected AFAP. When positive, genetic counseling and testing may be used to screen at-risk family members. If the family mutation is unknown, screening colonoscopy is recommended beginning at age 13 to 15 years, then every 4 years to age 28 years, and then every 3 years. These patients are often candidates for a total abdominal colectomy with ileorectal anastomosis because the limited polyposis in the rectum can usually be treated by colonoscopic snare excision. Prophylaxis with COX-2 inhibitors also may be appropriate. Because of the more subtle phenotype in these patients, it is important to rule out other familial syndromes such as HNPCC (Lynch’s syndrome) and the more common familial colorectal cancer.

**Hereditary Nonpolyposis Colon Cancer (Lynch’s Syndrome)**. HNPCC (Lynch’s syndrome) is more common than FAP, but is still extremely rare (1%–3% of all colon cancers). The genetic defects associated with HNPCC arise from errors in mismatch repair, the phenotypic result being MSI. HNPCC is inherited in an autosomal dominant pattern and is characterized by the development of colorectal carcinoma at an early age (average age, 40–45 years). Approximately 70% of affected individuals will develop colorectal cancer. Cancers appear in the proximal colon more often than in sporadic colorectal cancer and have a better prognosis regardless of stage. The risk of synchronous or metachronous colorectal carcinoma is 40%. HNPCC may also be associated with extracolonic malignancies, including endometrial carcinoma, which is most common, and ovarian, pancreas, stomach, small bowel, biliary, and urinary tract carcinomas. The diagnosis of HNPCC is made based on family history. The Amsterdam criteria for clinical diagnosis of HNPCC are three affected relatives with histologically verified adenocarcinoma of the large bowel (one must be a first-degree relative of one of the others) in two successive generations of a family with one patient diagnosed before age 50 years. The presence of other HNPCC-related carcinomas should raise the suspicion of this syndrome. In a patient with an established diagnosis of colorectal cancer, tumor testing for presence of mismatch repair gene products (immunohistochemistry) and/or MSI can sometimes serve as screening for this syndrome.

HNPCC results from mutations in mismatch repair genes, and like FAP, specific mutations are associated with different phenotypes. For example, mutations in PMS2 or MSH6 result in a more attenuated form of HNPCC when compared to mutations in other genes. MSH6 inactivation also appears to be associated with a higher risk for endometrial cancer. Further significance of these specific mutations remains to be determined.

Screening colonoscopy is recommended annually for at-risk patients beginning at either age 20 to 25 years or 10 years younger than the youngest age at diagnosis in the family, whichever comes first. Because of the high risk of endometrial carcinoma, transvaginal ultrasound or endometrial aspiration biopsy is also recommended annually after age 25 to 35 years. Because there is a 40% risk of developing a second colon cancer, total colectomy with ileorectal anastomosis is recommended once adenomas or a colon carcinoma is diagnosed. Annual proctoscopy is necessary because the risk of developing rectal cancer remains high. Similarly, prophylactic hysterectomy and bilateral...
salpingo-oophorectomy should be considered in women who have completed childbearing.

**Familial Colorectal Cancer.** Nonsyndromic familial colorectal cancer accounts for 10% to 15% of patients with colorectal cancer. The lifetime risk of developing colorectal cancer increases with a family history of the disease. The lifetime risk of colorectal cancer in a patient with no family history of this disease (average-risk population) is approximately 6%, but rises to 12% if one first-degree relative is affected and to 35% if two first-degree relatives are affected. Age of onset also impacts risk, and a diagnosis before the age of 50 years is associated with a higher incidence in family members. Screening colonoscopy is recommended every 5 years beginning at age 40 years or beginning 10 years before the age of the earliest diagnosed patient in the pedigree. While there are no specific genetic abnormalities that are associated with familial colorectal cancer, any of the defects found in either the LOH pathway or MSI pathway may be present in these patients.

**Prevention: Screening and Surveillance**

Because the majority of colorectal cancers are thought to arise from adenomatous polyps, preventive measures focus on identification and removal of these premalignant lesions. In addition, many cancers are asymptomatic, and screening may detect these tumors at an early and curable stage (Table 29-1). Although screening for colorectal cancer decreases the incidence of cancer and cancer-related mortality, the optimal method of screening remains controversial. Screening guidelines are meant for asymptomatic patients. Any patient with a gastrointestinal complaint (bleeding, change in bowel habits, pain, etc.) requires a complete evaluation, usually by colonoscopy.

**Fecal Occult Blood Testing.** FOBT is known to reduce colorectal cancer mortality by 33% and metastatic disease by 50%. However, FOBT is relatively insensitive, missing up to 50% of cancers and the majority of adenomas. Its specificity is low because 90% of patients with positive tests do not have colorectal cancer. Compliance with annual testing is low and costs are significant if one includes the colonoscopy examinations done to evaluate patients with positive FOBT. Nonetheless, the direct evidence that FOBT screening is efficacious and decreases both the incidence and mortality of colorectal cancer is so strong that national guidelines recommend annual FOBT screening for asymptomatic, average-risk Americans older than 50 years of age as one of several accepted strategies. Newer immunohistochemical methods for detecting human globin may prove to be more sensitive and specific. A positive FOBT test should be followed by colonoscopy.

**Flexible Sigmoidoscopy.** Screening by flexible sigmoidoscopy every 5 years may lead to a 60% to 70% reduction in mortality from colorectal cancer, chiefly by identifying high-risk individuals with adenomas. However, it is important to recognize that lesions in the proximal colon cannot be identified, and for this reason, flexible sigmoidoscopy has often been paired with air-contrast barium enema to detect transverse and right colon lesions. Patients found to have a polyp, cancer, or other lesion on flexible sigmoidoscopy will require colonoscopy.

**Fecal Occult Blood Testing and Flexible Sigmoidoscopy.** Several trials have shown that FOBT screening is least effective at detecting rectosigmoid cancers. This is precisely the area screened by flexible sigmoidoscopy; thus, the combination of the two tests has been suggested as a reasonable screening

</table>
strategy. Winawer and colleagues, in a study of 12,479 subjects, showed that the combination of FOBT annually with flexible sigmoidoscopy every 5 years resulted in lower mortality from colorectal cancer and better survival in patients with colorectal cancer. Such data led to the American Cancer Society recommendations that one of the acceptable screening regimens for average-risk Americans is the combination of FOBT annually and flexible sigmoidoscopy every 5 years; this combination was preferred over either test alone. The addition of air-contrast barium enema to assess the proximal colon may improve sensitivity as well.

**Colonoscopy.** Colonoscopy is currently the most accurate and most complete method for examining the large bowel. This procedure is highly sensitive for detecting even small polyps (<1 cm) and allows biopsy, polypectomy, control of hemorrhage, and dilation of strictures. However, colonoscopy does require mechanical bowel preparation, and the discomfort associated with the procedure requires conscious sedation in most patients. Colonoscopy is also considerably more expensive than other screening modalities and requires a well-trained endoscopist. The risk of a major complication after colonoscopy (perforation and dilation of strictures) is extremely low (0.2%–0.3%). Nevertheless, deaths have been reported.

**Air-Contrast Barium Enema.** Air-contrast barium enema is also highly sensitive for detecting polyps greater than 1 cm in diameter (90% sensitivity). Unfortunately, there are no studies proving its efficacy for screening large populations. Accuracy is greatest in the proximal colon but may be compromised in the sigmoid colon if there is significant diverticulosis. The major disadvantages of barium enema are the need for mechanical bowel preparation and the requirement for colonoscopy if a lesion is discovered.

**Computed Tomography Colonography (Virtual Colonoscopy).** Advances in imaging technology have created a number of less invasive, but highly accurate tools for screening. CT colonography makes use of helical CT technology and three-dimensional reconstruction to image the intraluminal colon. A present, patients require a mechanical bowel preparation. The colon is then insufflated with air, a spiral CT is performed, and both two-dimensional and three-dimensional images are generated. In the hands of a qualified radiologist, sensitivity appears to be as good as colonoscopy for colorectal cancers and polyps greater than 1 cm in size. Colonoscopy is required if a lesion is identified. CT colonography is also useful for imaging the proximal colon in cases of obstruction or if a colonoscopy cannot be completed. Limitations of this technique include false-positive results from retained stool, diverticular disease, haustral folds, motion artifacts, and an inability to detect flat adenomas.

**Guidelines for Screening.** Current American Cancer Society guidelines advocate screening for the average-risk population (asymptomatic, no family history of colorectal carcinoma, no personal history of polyps or colorectal carcinoma, no familial syndrome) beginning at age 50 years. Recommended procedures include yearly FOBT, flexible sigmoidoscopy every 5 years, FOBT and flexible sigmoidoscopy in combination, air-contrast barium enema every 5 years, or colonoscopy every 10 years. Patients with other risk factors should be screened earlier and more frequently (Table 29-2).

**Routes of Spread and Natural History**

Carcinoma of the colon and rectum arises in the mucosa. The tumor subsequently invades the bowel wall and eventually adjacent tissues and other viscera. Tumors may become bulky and circumferential, leading to colon obstruction. Local extension (especially in the rectum) may occasionally cause obstruction of other organs such as the ureter.

Regional lymph node involvement is the most common form of spread of colorectal carcinoma and usually precedes distant metastasis or the development of carcinomatosis. The likelihood of nodal metastasis increases with tumor size, poorly differentiated histology, lymphovascular invasion, and depth of invasion. The T stage (depth of invasion) is the single most significant predictor of lymph node spread. Carcinoma in situ (Tis) in which there is no penetration of the muscularis mucosa (basement membrane) has also been called high-grade dysplasia and should carry no risk of lymph node metastasis. Small lesions confined to the bowel wall (T1 and T2) are associated with lymph node metastasis in 5% to 20% of cases, whereas larger tumors that invade through the bowel wall or into adjacent organs (T3 and T4) are likely to have lymph node metastasis in more than 50% of cases. The number of lymph nodes with metastases correlates with the presence of distant disease and inversely with survival. Four or more involved lymph nodes predict a poor prognosis. In colon cancer, lymphatic spread usually follows the major venous outflow from the involved segment of the colon. Lymphatic spread from the rectum follows two routes. In the upper rectum, drainage ascends along the superior rectal vessels to the inferior mesenteric nodes. In the lower rectum, lymphatic drainage may course along the middle rectal vessels. Nodal spread along the inferior rectal vessels to the internal iliac nodes or groin is rare unless the tumor involves the anal canal or the proximal lymphatics are blocked with tumor (Fig. 29-23).

The most common site of distant metastasis from colorectal cancer is the liver. These metastases arise from hematogenous spread via the portal venous system. Like lymph node metastasis, the risk of hepatic metastasis increases with tumor size and tumor grade. However, even small tumors may produce distant metastasis. The lung is also a site of hematogenous spread, but this rarely occurs in isolation. Carcinomatosis (diffuse peritoneal metastases) occurs by peritoneal seeding and has a dismal prognosis.

**Staging and Preoperative Evaluation**

**Clinical Presentation.** Symptoms of colon and rectal cancers are nonspecific and generally develop when the cancer is locally advanced. The classic first symptoms are a change in bowel habits and rectal bleeding. Abdominal pain, bloating, and other signs of obstruction typically occur with larger tumors and suggest more advanced disease. Because of the caliber of the bowel and the consistency of the stool, left-sided tumors are more likely to cause obstruction than are right-sided tumors. Rectal tumors may cause bleeding, tenesmus, and pain. Alternatively, patients may be asymptomatic and/or present with unexplained anemia, weight loss, or poor appetite.

**Staging.** Colorectal cancer staging is based on tumor depth and the presence or absence of nodal or distant metastases. Older staging systems, such as the Dukes’ Classification and its Astler-Coller modification, have been replaced by the tumor-node-metastasis (TNM) staging system (Table 29-3). Stage I disease includes adenocarcinomas that are invasive through the muscularis mucosa but are confined to the submucosa (T1) or the muscularis propria (T2) in the absence of nodal metastases. Stage II disease consists of tumors that invade through the
bowel wall into the subserosa or nonperitonealized pericolic or perirectal tissues (T3) or into other organs or tissues through the visceral peritoneum (T4) without nodal metastases. Stage III disease includes any T stage with nodal metastases, and stage IV disease denotes distant metastases.

The preoperative evaluation usually identifies stage IV disease. In colon cancer, differentiating stages I, II, and III depends on examination of the resected specimen. In rectal cancer, endorectal ultrasound or MRI may predict the stage (ultrasound stage, uTNxS) preoperatively, but the final determination depends on pathologic examination of the resected tumor and adjacent lymph nodes (pathologic stage, pTNxS). Disease stage correlates with 5-year survival. Patients with stages I and II disease can expect excellent survival rates. The presence of nodal metastases (stage III) decreases survival (Table 29-4). The 5-year survival rate with stage IV disease is less than 16%. However, in well-selected patients, metastasectomy, especially of isolated liver or lung lesions, can result in cure. In rectal cancer, staging has been further refined, and outcomes suggest that subgroups of patients within each stage may have very different prognoses (Table 29-5). If the mesorectum around a rectal cancer is involved or threatened (only 1–2 mm of clearance), there is a very high likelihood of local recurrence and a poor

Prognosis. This circumferential or radial margin is probably best assessed preoperatively by MRI. Although nodal involvement is the single most important prognostic factor in colorectal carcinoma, tumor characteristics, such as degree of differentiation, mucinous or signet-ring cell histology, vascular invasion, and DNA aneuploidy, also adversely affect prognosis. Molecular profiling is currently being studied in an effort to further improve prognostic indicators.

Preoperative Evaluation. Once a colon or rectal carcinoma has been diagnosed, a staging evaluation should be undertaken. The colon must be evaluated for synchronous tumors, usually by colonoscopy. Synchronous disease will be present in up to 5% of patients. For rectal cancers, digital rectal examination and rigid or flexible proctoscopy with biopsy should be performed to assess tumor size, location, morphology, histology, and fixation. Endorectal ultrasound or MRI can be invaluable in staging rectal cancer and is used to classify the ultrasound T and N stage of rectal cancers (Fig. 29-24). A chest/abdominal/pelvic...
CT scan should be obtained to evaluate for distant metastases. Pelvic CT scan, and sometimes MRI, can be useful in large rectal tumors and in recurrent disease to determine the extent of local invasion. Among patients with obstructive symptoms, a water-soluble contrast study (Gastrografin enema) may be useful for delineating the degree of obstruction. It is important to avoid mechanical bowel preparation (for either colonoscopy or surgery) in a patient who appears to be obstructed. PET scan may be useful in evaluating lesions seen on CT scan and in patients in whom a risky or highly morbid operation is planned (pelvic exenteration, sacrectomy). Preoperative CEA is often obtained and may be useful for postoperative follow-up.

**Therapy for Colonic Carcinoma**

**Principles of Resection.** The objective in treatment of carcinoma of the colon is to remove the primary tumor along with its lymphovascular supply. Because the lymphatics of the colon accompany the main arterial supply, the length of bowel resected depends on which vessels are supplying the segment involved with the cancer. Any adjacent organ or tissue, such as the omentum, that has been invaded should be resected en bloc with the tumor. If all of the tumor cannot be removed, a palliative procedure should be considered, although it important to note that “debulking” is rarely effective in colorectal adenocarcinoma.

The presence of synchronous cancers or adenomas or a strong family history of colorectal neoplasms suggests that the entire colon is at risk for carcinoma (often called a field defect), and a subtotal or total colectomy should be considered. Metachronous tumors (a second primary colon cancer) identified during follow-up studies should be treated similarly. However, the surgeon must be aware of which mesenteric vessels have been ligated at the initial colectomy because that may influence the choice of procedure.

The number of lymph nodes recovered in the surgical specimen has long served as a proxy for the oncologic adequacy of resection. A number of studies previously have suggested that a minimum of 12 lymph nodes in the resected specimen are necessary for adequate staging. In addition, patients in whom more nodes are harvested have better long-term outcome. As such, a 12-node minimum has been suggested as an appropriate benchmark for assessing quality of care. However, several investigators recently have called this into question, noting that the number of lymph nodes examined does not correlate with staging, use of adjuvant chemotherapy, or patient survival. Others have suggested that the number of negative lymph nodes and/or the lymph node ratio (positive lymph nodes to total lymph nodes) may further improve staging. If unexpected metastatic disease is encountered at the time of a laparotomy, the decision about whether to proceed with resection of the primary tumor depends on the volume of distant disease, location and size of the primary tumor, the operation required to remove the primary tumor, and the operative approach. If the metastatic disease is low volume (isolated or potentially resectable liver lesions) and the resection of the primary tumor is straightforward (segmental abdominal colectomy), it is probably reasonable to proceed with resection. On the other hand, if the metastatic disease is high volume (carcinomatosis), especially if the primary tumor is minimally symptomatic, the operation should be aborted in order to facilitate early systemic chemotherapy. Some centers favor starting the operation with a diagnostic laparoscopy in cases where risk of discovering metastasis is high in order to minimize the magnitude of the operation should surgery be aborted. With recent advances in chemotherapy, many of these patients will never develop a complication from the primary tumor requiring surgical intervention.

Other palliative approaches include a bypass or proximal stoma for obstructing lesions.

**Stage-Specific Therapy**

**Stage 0 (Tis, NO, MO).** Polyps containing carcinoma in situ (high-grade dysplasia) carry no risk of lymph node metastasis. However, the presence of high-grade dysplasia increases the risk of finding an invasive carcinoma within the polyp. For this reason, these polyps should be excised completely, and pathologic margins should be free of dysplasia. Most pedunculated polyps and many sessile polyps may be completely removed endoscopically. These patients should be followed with frequent colonoscopy to ensure that the polyp has not recurred and that an invasive carcinoma has not developed. In cases where the polyp cannot be removed entirely, a segmental resection is recommended.

**Stage I: The Malignant Polyp (T1, NO, MO).** Occasionally a polyp that was thought to be benign will be found to harbor invasive carcinoma after polypectomy. Treatment of a malignant polyp is based on the risk of local recurrence and the risk of lymph node metastasis. The risk of lymph node metastases depends primarily on the depth of invasion. Invasive carcinoma in the head of a pedunculated polyp with no stalk involvement carries a low risk of metastasis (<1%) and may be completely resected endoscopically. However, lymphovascular invasion, poorly differentiated histology, or tumor within 1 mm of the resection margin greatly increases the risk of local recurrence and metastatic spread. Segmental colectomy is then indicated. Invasive carcinoma arising in a sessile polyp extends into the submucosa and is usually best treated with segmental colectomy (Fig. 29-25).

**Stages I and II: Localized Colon Carcinoma (T1-3, NO, MO).** The majority of patients with stages I and II colon cancer will be cured with surgical resection. Few patients with completely resected stage I disease will develop either local or distant recurrence, and adjuvant chemotherapy does not improve
survival in these patients. However, up to 46% of patients with completely resected stage II disease will ultimately die from colon cancer. For this reason, adjuvant chemotherapy has been suggested for selected patients with stage II disease (young patients, tumors with “high-risk” histologic findings). It remains controversial as to whether chemotherapy improves survival rates in these patients. Molecular profiling holds promise for improving patient selection in these early cancers.

**Stage III: Lymph Node Metastasis (Tany, N1, M0).** Patients with lymph node involvement are at significant risk for both local and distant recurrence, and adjuvant chemotherapy has been recommended routinely in these patients. 5-Fluorouracil-based regimens (with leucovorin) and oxaliplatin (FOLFOX) reduce recurrences and improve survival in this patient population.\footnote{9} It is important to note, however, that a subgroup of patients with stage III disease will do well without chemotherapy. MSI status in particular predicts good prognosis. Subset analysis from the CRISTAL trial has shown that patients with MSI-high stage III disease do not benefit from 5-fluorouracil-based chemotherapy. Molecular profiling, therefore, may be helpful in determining which stage III patients can safely avoid systemic chemotherapy.\footnote{52}

**Stage IV: Distant Metastasis (Tany, Nany, M1).** Survival is extremely limited in stage IV colon carcinoma. However, unlike many other malignancies, highly selected patients with isolated, resectable metastases may benefit from resection (metastasectomy). The most common site of metastasis is the liver. Of patients with systemic disease, approximately 15% will have metastases limited to the liver. Of these, 20% are potentially resectable for cure. Survival is improved in these patients (20%–40% 5-year survival) when compared to patients who do not undergo resection. Hepatic resection of synchronous metastases from colorectal carcinoma may be performed as a combined procedure or in two stages. All patients require adjuvant chemotherapy. The second most common site of metastasis is the lung, occurring in approximately 20% of patients with colorectal carcinoma. Although very few of these patients will be potentially resectable, among those who are (about 1%–2% of all colorectal cancer patients), long-term survival benefit is approximately 30% to 40%.\footnote{53} There are limited reports of successful resection of metastases in other sites (ovary and retroperitoneum are most common).

The remainder of patients with stage IV disease cannot be cured surgically, and therefore, the focus of treatment should be palliation.\footnote{54} Methods such as colonic stenting for obstructing lesions of the left colon also provide good palliation. More limited surgical intervention such as a diverting stoma or bypass procedure may be appropriate in patients with stage IV disease who develop obstruction. Hemorrhage in an unresectable tumor can sometimes be controlled with angiographic embolization. External beam radiation also has been used for palliation.

**Therapy for Rectal Carcinoma**

**Principles of Resection.** The biology of rectal adenocarcinoma is thought to be identical to the biology of colonic adenocarcinoma, and the operative principles of complete resection of the primary tumor, its lymphatic bed, and any other involved organ apply to surgical resection of rectal carcinoma. However, the anatomy of the pelvis and proximity of other structures (ureters, bladder, prostate, vagina, iliac vessels, and sacrum) make resection more challenging and often require a different approach than for colonic adenocarcinoma. Moreover, it is more difficult to achieve negative radial margins in rectal cancers that extend through the bowel wall because of the anatomic limitations of the pelvis. Therefore, local recurrence is higher than with similar stage colon cancers. However, unlike the intraperitoneal colon, the relative paucity of small bowel and other radiation-sensitive structures in the pelvis makes it easier to treat rectal tumors with radiation. Therapeutic decisions, therefore, are based on the location and depth of the tumor and its relationship to other structures in the pelvis.

**Local Therapy.** The distal 10 cm of the rectum are accessible transanally. For this reason, several local approaches have been proposed for treating rectal neoplasms. **Transanal excision** (full thickness or mucosal) is an excellent approach for noncircumferential, benign, villous adenomas of the rectum. **Transanal endoscopic microsurgery (TEM) and transanal minimally invasive surgery (TAMIS)** make use of a specially designed proctoscope, magnifying system, and instruments similar to those used in laparoscopy to allow local excision of lesions higher in the rectum (up to 15 cm). Although this technique has been used for selected T1, and some T2, carcinomas, local excision does not allow pathologic examination of the lymph nodes and might therefore understage patients. Moreover, local recurrence rates are high after transanal excision, and salvage surgery, while often curative, is associated with poorer survival than with initial radical surgery. Local excision of any rectal neoplasm should be considered an **excisional biopsy** because final pathologic examination of the specimen may reveal an invasive carcinoma that then mandates more radical therapy.

Ablative techniques, such as electrocautery or endovascular radiation, also have been used. The disadvantage of these techniques is that no pathologic specimen is retrieved to confirm the tumor stage. Fulguration is generally reserved for extremely high-risk patients with a limited life span who cannot tolerate more radical surgery.

**Radical Resection.** Radical resection is preferred to local therapy for most rectal carcinomas. Radical resection involves removal of the involved segment of the rectum along with its lymphovascular supply. Although any microscopically negative margin has been suggested to be adequate, most surgeons still attempt to obtain a 2-cm distal mural margin for curative resections.

**Total mesorectal excision (TME)** is a technique that uses sharp dissection along anatomic planes to ensure complete resection of the rectal mesentery during low and extended low anterior resections. For upper rectal or rectosigmoid resections, a partial mesorectal excision of at least 5 cm distal to the tumor appears adequate. TME both decreases local recurrence rates and improves long-term survival rates. Moreover, this technique is associated with less blood loss and less risk to the pelvic nerves and presacral plexus than is blunt dissection. The principles of TME should be applied to all radical resections for rectal cancer.

Recurrence of rectal cancer generally has a poor prognosis. Extensive involvement of other pelvic organs (usually occurring in the setting of tumor recurrence) may require a **pelvic exenteration**. The rectal and perineal portions of this operation are similar to an APR, but en bloc resection of the ureters, bladder, and prostate or uterus and vagina are also performed. A permanent colostomy and an ileal conduit to drain the urinary tract may be necessary. The sacrum may also be resected if necessary (sacrectomy) up to the level of the S2-S3 junction. These operations are best performed in tertiary centers with multidisciplinary teams consisting of a colon and rectal surgeon, urologist, neurosurgeon, and plastic surgeon.
Stage-Specific Therapy (Fig. 29-26). Pretreatment staging of rectal carcinoma often relies on endorectal ultrasound to determine the T and N status of a rectal cancer. Ultrasound is highly accurate at assessing tumor depth, but less accurate in diagnosing nodal involvement. Ultrasound evaluation can guide choice of therapy in most patients. MRI is useful to assess mesorectal involvement. When the radial margin is threatened or involved, neoadjuvant chemoradiation is recommended.

Stage 0 (Tis, N0, M0). Villous adenomas harboring carcinoma in situ (high-grade dysplasia) are ideally treated with local excision. A 1-cm margin should be obtained. Rarely, radical resection will be necessary if transanal excision is not technically possible (large circumferential lesions).

Stage I: Localized Rectal Carcinoma (T1-2, N0, M0). Although local excision has been used for small, favorable sessile uT1N0 and uT2N0 rectal cancers, local recurrence rates may be as high as 20% and 40%, respectively. For this reason, radical resection is strongly recommended in all good-risk patients. Lesions with unfavorable histologic characteristics and those located in the distal third of the rectum, in particular, are prone to recurrence. In high-risk patients and in patients who refuse radical surgery because of the risk of need for a permanent colostomy, local excision may be adequate, but strong consideration should be given to adjuvant or neoadjuvant chemoradiation to improve local control. The efficacy of adjuvant or neoadjuvant chemoradiation followed by transanal excision in patients who can tolerate radical surgery has been controversial. Early results from ACOSOG Z6041, in which patients with T2 rectal cancers received neoadjuvant chemoradiation followed by transanal excision, showed a pathologic complete response rate of 44%. Long-term outcomes, however, are not yet known.

Locally Advanced Rectal Cancer (Stages II and III)

Stage II: Localized Rectal Carcinoma (T3-4, N0, M0). Larger rectal tumors, especially if located in the distal rectum, are more likely to recur locally. There are two schools of thought, each differing in their approach to control local recurrences. Advocates of total mesorectal resection suggest that optimization of operative technique will obviate the need for any adjuvant chemoradiation to control local recurrence after resection of stages I, II, and III rectal cancers. The opposing school suggests that stages II and III rectal cancers will benefit from chemoradiation. They argue that such therapy reduces local recurrences and prolongs survival whether given preoperatively or postoperatively. The advantages of preoperative chemoradiation include tumor shrinkage, increased likelihood of resection and of a sphincter-sparing procedure, tumor downstaging by treating locally involved lymph nodes, and decreased risk to the small intestine. Disadvantages include possible overtreatment of early-stage tumors, impaired wound healing, and pelvic fibrosis increasing the risk of operative complications. Postoperative radiation allows accurate pathologic staging of the resected tumor and lymph nodes and avoids the wound healing problems.
associated with preoperative radiation. However, bulky tumors, tumors involving adjacent organs, and very low rectal tumors may be much more difficult to resect without preoperative radiation and may require a more extensive operation.

**Stage III: Lymph Node Metastasis (Tany, N1, M0).** Many surgeons now recommend chemotherapy and radiation either pre- or postoperatively for node-positive rectal cancers. The advantages and disadvantages are similar to those listed for stage II disease, except that the likelihood of overtreating an early-stage lesion is considerably less.

Over the past two decades, a wide variety of studies have addressed the issue of adjuvant and neoadjuvant therapy for locally advanced rectal cancer. Many of these studies demonstrated both improved local control and prolonged survival and resulted in the 1990 National Institutes of Health (NIH) consensus conference recommendation for postoperative chemoradiation therapy in these patients. There is little controversy regarding chemoradiation therapy for stage III (node-positive) disease. However, advances in surgical technique, such as TME, for locally advanced node-negative cancers (T3–4, N0; stage II) have improved local control with surgery alone, prompting some to abandon adjuvant chemoradiation in these patients, especially for those with cancers in the proximal rectum. Although the data from these studies are intriguing, other reports have shown that chemoradiation improves local control and survival even in patients who undergo TME. Thus, most colorectal surgeons in the United States continue to recommend adjuvant or neoadjuvant therapy for patients with locally advanced disease. Many European surgeons now rely heavily on MRI staging to determine the need for neoadjuvant chemoradiation. They use neoadjuvant chemoradiation if the radial margin is threatened or involved by the cancer or if an anal sphincter or other local organ invasion is present. In the United States, chemoradiation therapy is still recommended for all patients with stage III disease and the majority of patients with stage II disease. In select patients with T3 tumors, favorable histology, and negative radial margins, chemoradiation may not be necessary, but larger prospective studies are required before this approach can be recommended.

Appropriate timing of chemoradiation for locally advanced rectal cancer has been debated. Historically, preoperative chemoradiation has been advocated based on tumor shrinkage/dowstaging, improved resectability, and the possibility of performing a sphincter-sparing operation in some patients. In addition, the absence of small bowel adhesions in the pelvis may decrease toxicity. However, preoperative radiation therapy may increase operative complications and impair wound healing. Although preoperative endorectal ultrasound and MRI have improved our ability to stage rectal cancer, clinical “overstaging” can be problematic, and neoadjuvant therapy may therefore overtreat patients with pT1–2, N0 tumors. Advocates of postoperative radiation therapy cite more accurate pathologic staging and fewer operative/postoperative complications. However, large, bulky tumors may be unresectable or require a more extensive operation (APR, pelvic exenteration) without preoperative therapy. In addition, postoperative pelvic radiation may compromise function of the neorectum.

Comparisons of perioperative toxicity and oncologic outcome have been addressed by the German CAO/ARO/AIO-94 trial. In this study, pre- and postoperative chemoradiation were associated with equivalent acute toxicity and equivalent postoperative complication rates. Postoperative chemoradiation, however, doubled the risk of postoperative stricture formation. In addition, preoperative chemoradiation halved the risk of local recurrence (6% vs. 12%). Based on these data, most surgeons consider preoperative chemoradiation to be the most appropriate therapy for locally advanced rectal cancer.85

**Stage IV: Distant Metastasis (Tany, Nany, M1).** Like stage IV colon carcinoma, survival is limited in patients with distant metastasis from rectal carcinoma. Isolated hepatic and/or pulmonary metastases are rare, but when present may be resected for cure in selected patients.85 Some patients will require palliative procedures. Radical resection may be required to control pain, bleeding, or tenesmus, but highly morbid procedures such as pelvic exenteration and sacrectomy should generally be avoided in this setting. Local therapy using cautery, endovacitary radiation, or laser ablation may be adequate to control bleeding or prevent obstruction. Intraluminal stents may be useful in the uppermost rectum but often cause pain and tenesmus lower in the rectum. Occasionally, a proximal diverting colostomy will be required to alleviate obstruction. A mucus fistula should be created if possible to vent the distal colon. It is critical that the morbidity of any procedure be realistically weighed against potential benefit in these patients with limited life expectancy. The assistance of a palliative care team can be invaluable in this setting.84

**Follow-Up and Surveillance**

Patients who have been treated for one colorectal cancer are at risk for the development of recurrent disease (either locally or systemically) or metachronous disease (a second primary tumor). In theory, metachronous cancers should be preventable by using surveillance colonoscopy to detect and remove polyps before they progress to invasive cancer. For most patients, a colonoscopy should be performed within 12 months after the diagnosis of the original cancer (or sooner if the colon was not examined in its entirety prior to the original resection). If that study is normal, colonoscopy should be repeated every 3 to 5 years thereafter.

The optimal method of following patients for recurrent cancer remains controversial. The goal of close follow-up observation is to detect resectable recurrence and to improve survival. Re-resection of local recurrence and resection of distant metastasis to liver, lung, or other sites are often technically challenging and highly morbid, with only a limited chance of achieving long-term survival. Thus, only selected patients who would tolerate such an approach should be followed intensively. Because most recurrences occur within 2 years of the original diagnosis, surveillance focuses on this time period. Patients who have undergone local resection of rectal tumors probably should be followed with frequent endoscopic examinations (every 3–6 months for 3 years, then every 6 months for 2 years). CEA is often followed every 3 to 6 months for 2 years. CT scans are often performed annually for 5 years, but there are few data to support this practice. More intensive surveillance is appropriate in high-risk patients such as those with possible HNPPC syndrome or T3, N+ cancers. Although intensive surveillance improves detection of resectable recurrences, it is important to note that a survival benefit has never been proven. Therefore, the risks and benefits of intensive surveillance must be weighed and treatment individualized.

**Treatment of Recurrent Colorectal Carcinoma**

Between 20% and 40% of patients who have undergone curative intent surgery for colorectal carcinoma will eventually
develop recurrent disease. Most recurrences occur within the first 2 years after the initial diagnosis, but preoperative chemoradiation therapy may delay recurrence. While most of these patients will present with distant metastases, a small proportion will have isolated local recurrence and may be considered for salvage surgery. Recurrence after colon cancer resection usually occurs at the local site within the abdomen or in the liver or lungs. Resection of other involved organs may be necessary. Recurrence of rectal cancer can be considerably more difficult to manage because of the proximity of other pelvic structures. If the patient has not received chemotherapy and radiation, then adjuvant therapy should be administered prior to salvage surgery. Radical resection may require extensive resection of pelvic organs (pelvic exenteration with or without sacrectomy). Ideally, the aim of a salvage operation should be to resect all of the tumor with negative margins. However, if the ability to achieve a negative margin is in question, the addition of intraoperative radiation therapy (usually brachytherapy) can help improve local control. Pelvic MRI is useful for identifying tumor extension that would prevent successful resection (extension of tumor into the pelvic sidewall, involvement of the iliac vessels or bilateral sacral nerves, sacral invasion above the S2-S3 junction). Patients should also undergo a thorough preoperative evaluation to identify distant metastases (CT of chest, abdomen, and pelvis, and PET scan) before undergoing such an extensive procedure. Nevertheless, radical salvage surgery can prolong survival in selected patients.

**Minimally Invasive Techniques For Resection**

Laparoscopic colectomy for cancer has been controversial. Early reports of high port site recurrence dampened enthusiasm for this technique. The ability to perform an adequate oncologic resection for cancer has also been questioned. Several trials have led to rest many of these fears. The Clinical Outcomes of Surgical Therapy Study Group (COST), the Colon Carcinoma Laparoscopic or Open Resection (COLOR) trial, and the United Kingdom Medical Research Council Conventional versus Laparoscopic-Assisted Surgery in Colorectal Cancer (CLASSICC) trial all have shown oncologic equivalence between open and laparoscopic techniques. In these multi-institutional studies, the rates of cancer recurrence, survival, and quality of life were similar, suggesting that, in the hands of an appropriately trained surgeon, laparoscopic colectomy is appropriate for cancer. The recent introduction of robotic surgery offers an additional minimally invasive approach. Early studies suggest that robotic surgery may be the oncologic equivalent to laparoscopic surgery for colorectal cancer. A prospective, randomized, multicenter trial, Robotic versus Laparoscopic Resection for Rectal Cancer (ROLARR) is under way in hopes of answering this question.

**OTHER NEOPLASMS**

**Rare Colorectal Tumors**

**Carcinoid Tumors.** Carcinoid tumors occur most commonly in the gastrointestinal tract, and up to 25% of these tumors are found in the rectum. Most small rectal carcinoids are benign, and overall survival is greater than 80%. However, the risk of malignancy increases with size, and more than 60% of tumors greater than 2 cm in diameter are associated with distant metastases. Rectal carcinoids appear to be less likely to secrete vasoactive substances than carcinoids in other locations, and carcinoid syndrome is uncommon in the absence of hepatic metastases. Small carcinoids can be locally resected transanally. Larger tumors or tumors with obvious invasion into the muscularis require more radical surgery. Carcinoid tumors in the proximal colon are less common and are more likely to be malignant. Size also correlates with risk of malignancy, and tumors less than 2 cm in diameter rarely metastasize. However, the majority of carcinoid tumors in the proximal colon present as bulky lesions, and up to two thirds of patients will have metastatic spread at the time of diagnosis. These tumors should usually be treated with radical resection. Because carcinoid tumors are typically slow growing, patients with distant metastases may expect reasonably long survival. Symptoms of carcinoid syndrome can often be alleviated with somatostatin analogues (octreotide) and/or interferon-α. Tumor debulking can offer effective palliation in selected patients.

**Carcinoid Carcinomas.** Composite carcinoid carcinomas (adenocarcinoids) have histologic features of both carcinoid tumors and adenocarcinomas. The natural history of these tumors more closely parallels that of adenocarcinomas than carcinoid tumors, and regional and systemic metastases are common. Carcinoid carcinoma of the colon and rectum should be treated according to the same oncologic principles as followed for management of adenocarcinoma.

**Lipomas.** Lipomas occur most commonly in the submucosa of the colon and rectum. They are benign lesions, but rarely may cause bleeding, obstruction, or intussusception, especially when greater than 2 cm in diameter. Small asymptomatic lesions do not require resection. Larger lipomas should be resected by colonoscopic techniques or by a colotomy and enucleation or limited colectomy.

**Lymphoma.** Lymphoma involving the colon and rectum is rare but accounts for about 10% of all gastrointestinal lymphomas. The cecum is most often involved, probably as a result of spread from the terminal ileum. Symptoms include bleeding and obstruction, and these tumors may be clinically indistinguishable from adenocarcinomas. Bowel resection is the treatment of choice for isolated colorectal lymphoma. Adjuvant therapy may be given based on the stage of disease.

**Leiomyoma and Leiomyosarcoma.** Leiomyomas are benign tumors of the smooth muscle of the bowel wall and occur most commonly in the upper gastrointestinal tract. Most patients are asymptomatic, but large lesions can cause bleeding or obstruction. Because it is difficult to differentiate a benign leiomyoma from a malignant leiomyosarcoma, these lesions should be resected. Recurrence is common after local resection, but most small leiomyomas can be adequately treated with limited resection. Lesions larger than 5 cm should be treated with radical resection because the risk of malignancy is high.

Leiomyosarcoma is rare in the gastrointestinal tract. When this malignancy occurs in the large intestine, the rectum is the most common site. Symptoms include bleeding and obstruction. A radical resection is indicated for these tumors.

**Gastrointestinal Stromal Tumor.** These rare tumors occur most commonly in the stomach and small intestine, but 5% to 10% arise in the colon or rectum. They are often mistaken for leiomyomas. Thirty percent to 50% are malignant; thus all lesions should be resected.
Retrorectal/Presacral Tumors

Tumors occurring in the retrorectal space are rare. This region lies between the upper two thirds of the rectum and the sacrum above the rectosacral fascia. It is bound by the rectum anteriorly, the presacral fascia posteriorly, and the endopelvic fascia laterally (lateral ligaments). The retrorectal space contains multiple embryologic remnants derived from a variety of tissues (neuroectoderm, notochord, and hindgut). Tumors that develop in this space are often heterogeneous.

Congenital lesions are most common, comprising almost two thirds of retrorectal lesions. The remainder are classified as neurogenic, osseous, inflammatory, or miscellaneous lesions. Malignancy is more common in the pediatric population than in adults, and solid lesions are more likely to be malignant than are cystic lesions. Inflammatory lesions may be solid or cystic (abcess) and usually represent extensions of infection either in the perirectal space or in the abdomen.

Developmental cysts constitute the majority of congenital lesions and may arise from all three germ cell layers. Dermoid and epidermoid cysts are benign lesions that arise from the ectoderm. Enterogenous cysts arise from the primitive gut. Anterior meningocele and myelomingocele arise from herniation of the dural sac through a defect in the anterior sacrum. A “scimitar sign” (sacrum with a rounded, concave border without any bony destruction) is the pathognomonic radiographic appearance of this condition.

Solid lesions include teratomas, chordomas, neurologic tumors, or osseous lesions. Teratomas are true neoplasms and contain tissue from each germ cell layer. They often contain both cystic and solid components. Teratomas are more common in children than in adults, but when found in adults, 30% are malignant. Chordomas arise from the notochord and are the most common malignant tumor in this region. These are slow-growing, invasive cancers that show characteristic bony destruction. Neurogenic tumors include neurofibromas and sarcomas, neurilemomas, ependymomas, and ganglioneuromas. Osseous lesions include osteomas and bone cysts, as well as neoplasms such as osteogenic sarcoma, Ewing’s tumor, chondromyxosarcoma, and giant cell tumors.

Patients may present with pain (lower back, pelvic, or lower extremity), gastrointestinal symptoms, or urinary tract symptoms. Most lesions are palpable on digital rectal examination. While plain X-rays and CT scans often are used to evaluate these lesions, pelvic MRI is the most sensitive and specific imaging study. Myelogram is occasionally necessary if there is central nervous system involvement. Treatment is almost always surgical resection. The approach depends in part on the nature of the lesion and its location. Lesions high in the pelvis may be approached via a transabdominal route, whereas low lesions may be resected transsacrally. Intermediate lesions may require a combined abdominal and sacral operation. Although survival is excellent after resection of benign lesions, local recurrence is not uncommon. Prognosis after resection of malignant lesions is highly variable and reflects the biology of the underlying tumor.

The role of biopsy in this setting has been controversial. Historically, the recommendation was to avoid biopsy because of the risk of infection or needle tract seeding. This recommendation has recently been challenged, especially for large and/or unusual tumors that would be better treated with multimodality neoadjuvant therapy (sarcomas, for example). A recent study confirmed the utility of needle biopsy of solid lesions and refuted concerns about needle tract seeding. As such, most solid lesions should be biopsied regardless of resectability. Biopsy of cystic lesions, especially meningoces, should still be avoided because of the risk of infection.

Anal Canal and Perianal Tumors

Cancers of the anal canal are uncommon and account for approximately 2% of all colorectal malignancies. Neoplasms of the anal canal have traditionally been divided into those affecting the anal margin (distal to the dentate line) and those affecting the anal canal (proximal to the dentate line) based on lymphatic drainage patterns. Lymphatics from the anal canal proximal to the dentate line drain cephalad via the superior rectal lymphatics to the inferior mesenteric nodes and laterally along both the middle rectal vessels and inferior rectal vessels through the ischiorectal fossa to the internal iliac nodes. Lymph from the anal canal distal to the dentate line usually drains to the inguinal nodes. It can also drain to the superior rectal lymph nodes or along the inferior rectal lymphatics to the ischiorectal fossa if primary drainage routes are blocked with tumor (Fig. 29-27).

A more clinically useful classification divides anal lesions into those that are perianal (can be completely visualized with gentle eversion of the buttocks) and those that are intra-anal (cannot be completely visualized with gentle eversion of the buttocks). In many cases, therapy depends on whether the tumor is perianal or intra-anal.

Squamous Intraepithelial Lesions. Anal canal and perianal dysplasia have long had a potpourri of nomenclature. Anal intraepithelial neoplasia (AIN), Bowen’s disease, and carcinoma in situ all refer to human papillomavirus (HPV)-induced dysplasia. Because these entities are pathologically identical, there has been a recent effort to standardize nomenclature. High-grade squamous intraepithelial lesions (HSIL) include high- and intermediate-grade dysplasia, AIN2 and AIN3, Bowen’s
disease, and carcinoma in situ. Low-grade squamous intraepithelial lesions (LSIL) include low-grade dysplasia and AIN1,93

HSIL is a precursor to an invasive squamous cell carcinoma (epidermoid carcinoma). HSIL may appear as a plaque-like lesion or may only be apparent with high-resolution anoscopy and application of acetic acid or Lugol’s iodine solution. Both HSIL and LSIL are associated with infection with HPV, especially types 16 and 18. The incidence of both squamous intraepithelial lesions and epidermoid carcinoma of the anus has increased dramatically among human immunodeficiency virus (HIV)–positive, homosexual men. This increase is thought to result from increased rates of HPV infection along with HIV-induced immunosuppression. Treatment of HSIL is ablation. Because of a high recurrence and/or reinfection rate, these patients require extremely close surveillance. High-risk patients should be followed with frequent anal Papanicolaou (Pap) smears every 3 to 6 months. An abnormal Pap smear should be followed by an examination under anesthesia and anal mapping using high-resolution anoscopy. High-resolution anoscopy shows areas with abnormal telangiectasias that are consistent with high-grade dysplasia (HSIL). Many centers now consider this technique for repeated ablation of HSIL to be the optimal method for following these patients. It should be noted, however, that the practice has not been universally adopted, and it is unclear whether close surveillance in lower risk (nonimmunosuppressed) patients is necessary. Rarely, extensive disease may require resection with flap closure. Medical therapy for HPV has also been proposed. Topical immunomodulators such as imiquimod (Aldara) have been shown to induce regression in some series.94 Topical 5-fluorouracil has also been used in this setting. Finally, the introduction of a vaccine against HPV may help decrease the incidence of this disease in the future.

Epidermoid Carcinoma. Epidermoid carcinoma of the anus includes squamous cell carcinoma, cloacogenic carcinoma, transitional carcinoma, and basaloid carcinoma. The clinical behavior and natural history of these tumors are similar. Epidermoid carcinoma is a slow-growing tumor and usually presents as an intra-anal or perianal mass. Pain and bleeding may be present. Perianal epidermoid carcinoma may be treated in a similar fashion as squamous cell carcinoma of the skin in other locations because wide local excision can usually be achieved without resecting the anal sphincter. Intra-anal epidermoid carcinoma cannot be excised locally, and first-line therapy relies on chemotherapy and radiation (the Nigro protocol: 5-fluorouracil, mitomycin C, and 30 Gy of external beam radiation).

More than 80% of these tumors can be cured by using this regimen. Recurrence usually requires radical resection (APR). Metastasis to inguinal lymph nodes is a poor prognostic sign.

Verrucous Carcinoma (Buschke-Lowenstein Tumor, Giant Condyloma Acuminata). Verrucous carcinoma is a locally aggressive form of condyloma acuminata. Although these lesions do not metastasize, they can cause extensive local tissue destruction and may be grossly indistinguishable from epidermoid carcinoma. Wide local excision is the treatment of choice when possible, but radical resection may sometimes be required. Very large lesions may respond to external beam radiation, but resection is almost always required.

Basal Cell Carcinoma. Basal cell carcinoma of the anus is rare and resembles basal cell carcinoma elsewhere on the skin (raised, pearly edges with central ulceration). This is a slow-growing tumor that rarely metastasizes. Wide local excision is the treatment of choice, but recurrence occurs in up to 30% of patients. Radical resection and/or radiation therapy may be required for large lesions.

Adenocarcinoma. Adenocarcinoma of the anus is extremely rare and usually represents downward spread of a low rectal adenocarcinoma. Adenocarcinoma may occasionally arise from the anal glands or may develop in a chronic fistula. Radical resection with or without adjuvant chemoradiation is usually required.

Extramammary perianal Paget’s disease is adenocarcinoma in situ arising from the apocrine glands of the perianal area. The lesion is typically plaque-like and may be indistinguishable from HSIL. Characteristic Paget’s cells are seen histologically. These tumors are often associated with a synchronous gastrointestinal adenocarcinoma, so a complete evaluation of the intestinal tract should be performed. Wide local excision is usually adequate treatment for perianal Paget’s disease.

Melanoma. Anorectal melanoma is rare, comprising less than 1% of all anorectal malignancies and 1% to 2% of melanomas. Despite many advances in the treatment of melanoma, prognosis for patients with anorectal disease remains poor. Overall 5-year survival is less than 10%, and many patients present with systemic metastasis and/or deeply invasive tumors at the time of diagnosis. A few patients with anorectal melanoma, however, present with isolated local or locoregional disease that is potentially resectable for cure, and both radical resection (APR) and wide local excision have been advocated. Recurrence is common and usually occurs systemically regardless of the initial surgical procedure. Local resection with clear margins does not increase the risk of local or regional recurrence, and APR offers no survival advantage over local excision. Because of the morbidity associated with APR, wide local excision is recommended for initial treatment of localized anal melanoma. In some patients, wide local excision may not be technically feasible, and APR may be required if the tumor involves a significant portion of the anal sphincter or is circumferential. The addition of adjuvant chemotherapy, biochemotherapy, vaccines, or radiotherapy may be of benefit in some patients, but efficacy remains unproven.95

OTHER BENIGN COLORECTAL CONDITIONS

Rectal Prolapse and Solitary Rectal Ulcer Syndrome

Rectal Prolapse. Rectal prolapse refers to a circumferential, full-thickness protrusion of the rectum through the anus and has also been called “first-degree” prolapse, “complete” prolapse, or procidentia. Internal prolapse occurs when the rectal wall is susceps but does not protrude and is probably more accurately described as internal intussusception. Mucosal prolapse is a partial-thickness protrusion often associated with hemorrhoidal disease and is usually treated with banding or hemorrhoidectomy.

In adults, this condition is far more common among women, with a female-to-male ratio of 6:1. Prolapse becomes more prevalent with age in women and peaks in the seventh decade of life. In men, prevalence is unrelated to age.

Symptoms include tenesmus, a sensation of tissue protruding from the anus that may or may not spontaneously reduce, and a sensation of incomplete evacuation. Mucus discharge and leakage may accompany the protrusion. Patients also present with a myriad of functional complaints, from incontinence and diarrhea to constipation and outlet obstruction.
A thorough preoperative evaluation, including colonic transit studies, anorectal manometry, tests of pudendal nerve terminal motor latency, EMG, and cinedefecography, may be useful. The colon should be evaluated by colonoscopy, air-contrast barium enema, or CT colonography to exclude neoplasms or diverticular disease. Cardiopulmonary condition should be thoroughly evaluated because comorbidities may influence the choice of surgical procedure.

The primary therapy for rectal prolapse is surgery, and more than 100 different procedures have been described to treat this condition. Operations can be categorized as either abdominal or perineal. Abdominal operations have taken three major approaches: (a) reduction of the perineal hernia and closure of the cul-de-sac (Moschowitz repair); (b) fixation of the rectum, either with a prosthetic sling (Ripsten and Wells rectopexy) or by suture rectopexy; or (c) resection of redundant sigmoid colon (Fig. 29-28). In some cases, resection is combined with rectal fixation (resection rectopexy). Abdominal rectopexy with or without resection also is increasingly performed laparoscopically or robotically. Perineal approaches have focused on tightening the anus with a variety of prosthetic materials, reefing the rectal mucosa (Delorme procedure), or resecting the prolapsed bowel from the perineum (perineal rectosigmoidectomy or Altemeier procedure) (Fig. 29-29).

Because rectal prolapse occurs most commonly in elderly women, the choice of operation depends in part on the patient’s overall medical condition. Abdominal rectopexy (with or without sigmoid resection) offers the most durable repair, with recurrence occurring in less than 10% of patients. Perineal rectosigmoidectomy avoids an abdominal operation and may be preferable in high-risk patients but is associated with a higher recurrence rate. Reefing the rectal mucosa is effective for patients with limited prolapse. Anal encirclement procedures generally have been abandoned.

**Solitary Rectal Ulcer Syndrome.** Solitary rectal ulcer syndrome and colitis cystica profunda are commonly associated with internal intussusception. Patients may complain of pain, bleeding, mucus discharge, or outlet obstruction. In solitary rectal ulcer syndrome, one or more ulcers are present in the distal rectum, usually on the anterior wall. In colitis cystica profunda, nodules or a mass may be found in a similar location. Evaluation should include anorectal manometry, defecography, and either colonoscopy or barium enema to exclude other diagnoses. Biopsy of an ulcer or mass is mandatory to exclude malignancy or infection due to cytomegalovirus (CMV) in an immunosuppressed patient. Nonoperative therapy (high-fiber diet, defecation training to avoid straining, and laxatives or enemas) is effective in the majority of patients. Biofeedback has also been reported to be effective in some patients. Surgery (either abdominal or perineal repair of prolapse as described earlier) is reserved for highly symptomatic patients who have failed all medical interventions.72

**Volvulus**

Volvulus occurs when an air-filled segment of the colon twists about its mesentery. The sigmoid colon is involved in up to 90% of cases, but volvulus can involve the cecum (<20%) or transverse colon. A volvulus may reduce spontaneously, but more commonly produces bowel obstruction, which can progress to strangulation, gangrene, and perforation. Chronic constipation may produce a large, redundant colon (chronic megacolon) that predisposes to volvulus, especially if the mesenteric base is narrow.

The symptoms of volvulus are those of acute bowel obstruction. Patients present with abdominal distention, nausea, and vomiting. Symptoms rapidly progress to generalized abdominal pain and tenderness. Fever and leukocytosis are heralds of gangrene and/or perforation. Occasionally, patients will report a long history of intermittent obstructive symptoms and distention, suggesting intermittent chronic volvulus.

**Sigmoid Volvulus.** Sigmoid volvulus can often be differentiated from cecal or transverse colon volvulus by the appearance of plain X-rays of the abdomen. Sigmoid volvulus produces a characteristic bent inner tube or coffee bean appearance, with the convexity of the loop lying in the right upper quadrant (opposite the site of obstruction). Gastrografin enema shows a narrowing at the site of the volvulus and a pathognomonic bird’s beak (Fig. 29-30).

Unless there are obvious signs of gangrene or peritonitis, the initial management of sigmoid volvulus is resuscitation followed by endoscopic detorsion. Detorsion is usually most easily accomplished by using a rigid proctoscope, but a flexible sigmoidoscope or colonoscope may also be effective. A rectal tube may be inserted to maintain decompression. Although these techniques are successful in reducing sigmoid volvulus in the majority of patients, the risk of recurrence is high (up to 40%). For this reason, an elective sigmoid colectomy should be performed after the patient has been stabilized and undergone an adequate bowel preparation.

Clinical evidence of gangrene or perforation mandates immediate surgical exploration without an attempt at endoscopic decompression. Similarly, the presence of necrotic mucosa, ulceration, or dark blood noted on endoscopy examination suggests strangulation and is an indication for operation.
If dead bowel is present at laparotomy, a sigmoid colectomy with end colostomy (Hartmann’s procedure) may be the safest operation to perform.

Cecal Volvulus. Cecal volvulus results from nonfixation of the right colon. In the majority of cases, rotation occurs around the ileocolic blood vessels and vascular impairment occurs early, although 10% to 30% of the cecum folds upon itself (cecal bascule). Plain X-rays of the abdomen show a characteristic kidney-shaped, air-filled structure in the left upper quadrant (opposite the site of obstruction), and a Gastrografin enema confirms obstruction at the level of the volvulus.

Unlike sigmoid volvulus, cecal volvulus can almost never be detorsed endoscopically. Moreover, because vascular compromise occurs early in the course of cecal volvulus, surgical exploration is necessary when the diagnosis is made. Right hemicolectomy with a primary ileocolic anastomosis can usually be performed safely and prevents recurrence. Simple detorsion or detorsion and cecopexy are associated with a high rate of recurrence.

Transverse Colon Volvulus. Transverse colon volvulus is extremely rare. Nonfixation of the colon and chronic constipation with megacolon may predispose to transverse colon volvulus. The radiographic appearance of transverse colon volvulus resembles sigmoid volvulus, but Gastrografin enema will reveal a more proximal obstruction. Although colonoscopic detorsion is occasionally successful in this setting, most patients require emergent exploration and resection.

Megacolon

Megacolon describes a chronically dilated, elongated, hypertrophied large bowel. Megacolon may be congenital or acquired and is usually related to chronic mechanical or functional obstruction. In general, the degree of megacolon is related to the duration of obstruction. Evaluation must always include examination of the colon and rectum (either endoscopically or radiographically) to exclude a surgically correctable mechanical obstruction.

Congenital megacolon caused by Hirschsprung’s disease results from the failure of migration of neural crest cells to the distal large intestine. The resulting absence of ganglion cells in the distal colon results in a failure of relaxation and causes a functional obstruction. The proximal, healthy bowel becomes progressively dilated. Surgical resection of the aganglionic segment is curative. Although Hirschsprung’s disease primarily is a disease of infants and children, it occasionally presents
later in adulthood, especially if an extremely short segment of the bowel is affected (ultrashort-segment Hirschsprung’s disease).

Acquired megacolon may result from infection or chronic constipation. Infection with the protozoan *Trypanosoma cruzi* (*Chagas’ disease*) destroys ganglion cells and produces both megacolon and megaesophagus. Chronic constipation from slow transit or secondary to medications (especially anticholinergic medications) or neurologic disorders (paraplegia, poliomyelitis, amyotrophic lateral sclerosis, multiple sclerosis) may produce progressive colonic dilatation. Diverting ileostomy or subtotal colectomy with an ileorectal anastomosis is occasionally necessary in these patients.

**Colonic Pseudo-obstruction (Ogilvie’s Syndrome)**

Colonic pseudo-obstruction (Ogilvie’s syndrome) is a functional disorder in which the colon becomes massively dilated in the absence of mechanical obstruction. Pseudo-obstruction most commonly occurs in hospitalized patients and is associated with the use of narcotics, bed rest, and comorbid disease. Pseudo-obstruction is thought to result from autonomic dysfunction and severe adynamic ileus. The diagnosis is made based on the presence of massive dilatation of the colon (usually predominantly the right and transverse colon) in the absence of a mechanical obstruction. Initial treatment consists of cessation of narcotics, anticholinergics, or other medications that may contribute to ileus. Strict bowel rest and intravenous hydration are crucial. Most patients will respond to these measures. In patients who fail to improve, colonoscopic decompression often is effective. However, this procedure is technically challenging, and great care must be taken to avoid causing perforation. Up to 40% of patients recur. Intravenous neostigmine (an acetylcholinesterase inhibitor) also is extremely effective in decompressing the dilated colon and is associated with a low rate of recurrence (20%). However, neostigmine may produce transient but profound bradycardia and may be inappropriate in patients with cardiopulmonary disease. Because the colonic dilatation is typically greatest in the proximal colon, placement of a rectal tube is rarely effective. It is crucial to exclude mechanical obstruction (usually with a Gastrografin enema) prior to medical or endoscopic treatment.

**Ischemic Colitis**

Intestinal ischemia occurs most commonly in the colon. Unlike small bowel ischemia, colonic ischemia rarely is associated with major arterial or venous occlusion. Instead, most colonic ischemia appears to result from low flow and/or small vessel occlusion. Risk factors include vascular disease, diabetes mellitus, vasculitis, hypotension, and tobacco use. In addition, ligation of the inferior mesenteric artery during aortic surgery predisposes to colonic ischemia. Occasionally, thrombosis or embolism may cause ischemia. Although the splenic flexure is the most common site of ischemic colitis, any segment of the colon may be affected. The rectum is relatively spared because of its rich collateral circulation.
Signs and symptoms of ischemic colitis reflect the extent of bowel ischemia. In mild cases, patients may have diarrhea (usually bloody) without abdominal pain. With more severe ischemia, intense abdominal pain (often out of proportion to the clinical examination), tenderness, fever, and leukocytosis are present. Peritonitis and/or systemic toxicity are signs of full-thickness necrosis and perforation.

The diagnosis of ischemic colitis is often based on the clinical history and physical examination. Plain films may reveal thumb printing, which results from mucosal edema and submucosal hemorrhage. CT often shows nonspecific colonic wall thickening and pericolic fat stranding. Angiography is usually not helpful because major arterial occlusion is rare. While sigmoidoscopy may reveal characteristic dark, hemorrhagic mucosa, the risk of precipitating perforation is high. For this reason, sigmoidoscopy is relatively contraindicated in any patient with significant abdominal tenderness. Contrast studies (Gastrografin or barium enema) are similarly contraindicated during the acute phase of ischemic colitis.

Treatment of ischemic colitis depends on clinical severity. Unlike ischemia of the small bowel, the majority of patients with ischemic colitis can be treated medically. Bowel rest and broad-spectrum antibiotics are the mainstay of therapy, and 80% of patients will recover with this regimen. Hemodynamic parameters should be optimized, especially if hypotension and low flow appear to be the inciting cause. Long-term sequelae include stricture (10%–15%) and chronic segmental ischemia (15%–20%). Colonoscopy should be performed after recovery to evaluate strictures and to rule out other diagnoses such as inflammatory bowel disease or malignancy. Failure to improve after 2 to 3 days of medical management, progression of symptoms, and deterioration in clinical condition are indications for surgical exploration. In this setting, all necrotic bowel should be resected. Primary anastomosis should be avoided. Occasionally, repeated exploration (a second-look operation) may be necessary.

**Infectious Colitis**

**Pseudomembranous Colitis (Clostridium difficile Colitis).** Pseudomembranous colitis is caused by *C. difficile*, a gram-positive anaerobic bacillus. *C. difficile colitis* is extremely common and is the leading cause of nosocomially acquired diarrhea. The spectrum of disease ranges from watery diarrhea to fulminant, life-threatening colitis. *C. difficile* is carried in the large intestine of many healthy adults. Colitis is thought to result from overgrowth of this organism after depletion of the normal commensal flora of the gut with the use of antibiotics. Although clindamycin was the first antimicrobial agent associated with *C. difficile colitis*, almost any antibiotic may cause this disease. Moreover, although the risk of *C. difficile* colitis increases with prolonged antibiotic use, even a single dose of an antibiotic may cause the disease. Immunosuppression, medical comorbidities, prolonged hospitalization or nursing home residence, and bowel surgery increase the risk.

The pathogenic changes associated with *C. difficile* colitis result from production of two toxins: *toxin A* (an enterotoxin) and *toxin B* (a cytotoxin). Diagnosis of this disease was traditionally made by culturing the organism from the stool. Detection of one or both toxins (either by cytotoxic assays or by immunoassays) has proven to be more rapid, sensitive, and specific. The diagnosis may also be made endoscopically by detection of characteristic ulcers, plaques, and pseudomembranes.

Management should include immediate cessation of the offending antimicrobial agent. Patients with mild disease (diarrhea but no fever or abdominal pain) may be treated as outpatients with a 10-day course of oral metronidazole. Oral vancomycin is a second-line agent used in patients allergic to metronidazole or in patients with recurrent disease. More severe diarrhea associated with dehydration and/or fever and abdominal pain is best treated with bowel rest, intravenous hydration, and oral metronidazole or vancomycin. Proctosigmoiditis may respond to vancomycin enemas. Recurrent colitis occurs in up to 20% of patients and may be treated by a longer course of oral metronidazole or vancomycin (up to 1 month) or rifaximin (a ramapycin derivative). Reintroduction of normal flora by ingestion of probiotics or stool transplantation has been suggested as a possible treatment for recurrent or refractory disease. Fulminant colitis, characterized by septicaemia and/or evidence of perforation, requires emergent laparotomy. A total abdominal colectomy with end ileostomy may be lifesaving. Over the past decade, *C. difficile* colitis has increased in prevalence, and new, more virulent strains have appeared, making this disease increasingly challenging to treat.

**Other Infectious Colitides.** A variety of other infections with bacteria, parasites, fungi, or viruses may cause colonic inflammation. Common bacterial infections include enterotoxic E. coli, Campylobacter jejuni, Yersinia enterocolitica, Salmonella typhi, Shigella, and *N. gonorrhoeae*. Less commonly, *Mycobacterium tuberculosis*, *Mycobacterium bovis*, *Actinomyces israelii*, or Treponema pallidum (syphilis) may cause colitis or proctitis. Parasitic infections such as amebiasis, cryptosporidiosis, and giardiasis are also relatively common. Fungal infections (*Candida* species, histoplasmosis) are extremely rare in otherwise healthy individuals. The most common viral infections that produce colitic symptoms are HIV, herpes simplex viruses, and CMV.

Most symptoms are nonspecific and consist of diarrhea (with or without bleeding), crampy abdominal pain, and malaise. A thorough history may offer clues to the etiology (other medical conditions, especially immunosuppression; recent travel or exposures; and ingestions). Diagnosis is usually made by identification of a pathogen in the stool, either by microscopy or culture. Serum immunoassays may also be useful (amebiasis, HIV, CMV). Occasionally, endoscopy with biopsy may be required. Treatment is tailored to the infection.

**ANORECTAL DISEASES**

Any patient with anal/perianal symptoms requires a careful history and physical, including a digital rectal examination. Other studies such as defecography, manometry, CT scan, MRI, contrast enema, endoscopy, and exam under anesthesia may be required to arrive at an accurate diagnosis.

**Hemorrhoids**

Hemorrhoids are cushions of submucosal tissue containing venules, arterioles, and smooth muscle fibers that are located in the anal canal (see Fig. 29–4). Three hemorrhoidal cushions are found in the left lateral, right anterior, and right posterior positions. Hemorrhoids are thought to function as part of the continence mechanism and aid in complete closure of the anal canal at rest. Because hemorrhoids are a normal part of anorectal anatomy, treatment is only indicated if they become symptomatic. Excessive straining, increased abdominal
pressure, and hard stools increase venous engorgement of the hemorrhoidal plexus and cause prolapse of hemorrhoidal tissue. Bleeding, thrombosis, and symptomatic hemorrhoidal prolapse may result.

External hemorrhoids are located distal to the dentate line and are covered with anoderm. Because the anoderm is richly innervated, thrombosis of an external hemorrhoid may cause significant pain. It is for this reason that external hemorrhoids should not be ligated or excised without adequate local anesthetic. A skin tag is redundant fibrotic skin at the anal verge, often persisting as the residua of a thrombosed external hemorrhoid. Skin tags are often confused with symptomatic hemorrhoids. External hemorrhoids and skin tags may cause itching and difficulty with hygiene if they are large. Treatment of external hemorrhoids and skin tags is only indicated for symptomatic relief.

Internal hemorrhoids are located proximal to the dentate line and covered by insensate anorectal mucosa. Internal hemorrhoids may prolapse or bleed, but rarely become painful unless they develop thrombosis and necrosis (usually related to severe prolapse, incarceration, and/or strangulation). Internal hemorrhoids are graded according to the extent of prolapse. First-degree hemorrhoids bulge into the anal canal and may prolapse beyond the dentate line on straining. Second-degree hemorrhoids prolapse through the anus but reduce spontaneously. Third-degree hemorrhoids prolapse through the anal canal and require manual reduction. Fourth-degree hemorrhoids prolapse but cannot be reduced and are at risk for strangulation.

Combined internal and external hemorrhoids straddle the dentate line and have characteristics of both internal and external hemorrhoids. Hemorrhoidectomy is often required for large, symptomatic, combined hemorrhoids. Postpartum hemorrhoids result from straining during labor, which results in edema, thrombosis, and/or strangulation. Hemorrhoidectomy is often the treatment of choice, especially if the patient has had chronic hemorrhoidal symptoms. Portal hypertension was long thought to increase the risk of hemorrhoidal bleeding because of the anastomoses between the portal venous system (middle and upper hemorrhoidal plexuses) and the systemic venous system (inferior rectal plexuses). It is now understood that hemorrhoidal disease is no more common in patients with portal hypertension than in the normal population. Rectal varices, however, may occur and may cause hemorrhage in these patients. In general, rectal varices are best treated by lowering portal venous pressure. Rarely, suture ligation may be necessary if massive bleeding persists. Surgical hemorrhoidectomy should be avoided in these patients because of the risk of massive, difficult-to-control variceal bleeding.

Treatment

Medical Therapy. Bleeding from first- and second-degree hemorrhoids often improves with the addition of dietary fiber, stool softeners, increased fluid intake, and avoidance of straining. Associated pruritus often may improve with improved hygiene. Many over-the-counter topical medications are desiccants and are relatively ineffective for treating hemorrhoidal symptoms.

Rubber Band Ligation. Persistent bleeding from first-, second-, and selected third-degree hemorrhoids may be treated by rubber band ligation.

Mucosa located 1 to 2 cm proximal to the dentate line is grasped and pulled into a rubber band applier. After firing the ligator, the rubber band strangulates the underlying tissue, causing scarring and preventing further bleeding or prolapse (Fig. 29-31). In general, only one or two quadrants are banded per visit. Severe pain will occur if the rubber band is placed at or distal to the dentate line where sensory nerves are located. Other complications of rubber band ligation include urinary retention, infection, and bleeding. Urinary retention occurs in approximately 1% of patients and is more likely if the ligation has inadvertently included a portion of the internal sphincter. Necrotizing infection is an uncommon, but life-threatening complication. Severe pain, fever, and urinary retention are early signs of infection and should prompt immediate evaluation of the patient usually with an exam under anesthesia. Treatment includes debridement of necrotic tissue, drainage of associated abscesses, and broad-spectrum antibiotics. Bleeding may occur approximately 7 to 10 days after rubber band ligation, at the time when the ligated pedicle necroses and sloughs. Bleeding is usually self-limited, but persistent hemorrhage may require exam under anesthesia and suture ligation of the pedicle.

Infrared Photocoagulation. Infrared photocoagulation is an effective office treatment for small first- and second-degree hemorrhoids. The instrument is applied to the apex of each hemorrhoid to coagulate the underlying plexus. All three quadrants may be treated during the same visit. Larger hemorrhoids and hemorrhoids with a significant amount of prolapse are not effectively treated with this technique.

Sclerotherapy. The injection of bleeding internal hemorrhoids with sclerosing agents is another effective office technique for treatment of first-, second-, and some third-degree hemorrhoids. One to 3 mL of a sclerosing solution (phenol in olive oil, sodium morrhuate, or quinine urea) is injected into the submucosa of each hemorrhoid. Few complications are associated with sclerotherapy, but injection and fibrosis have been reported.

Excision of Thrombosed External Hemorrhoids. Acutely thrombosed external hemorrhoids generally cause intense pain and a palpable perianal mass during the first 24 to 72 hours after thrombosis. The thrombosis can be effectively treated with an elliptical excision performed in the office under local anesthesia. Because the clot is usually loculated, simple incision and drainage is rarely effective. After 72 hours, the clot begins to resorb, and the pain resolves spontaneously. Excision is unnecessary, but sitz baths and analgesics are often helpful.

Operative Hemorrhoidectomy. A number of surgical procedures have been described for elective resection of symptomatic hemorrhoids. All are based on decreasing blood flow to the hemorrhoidal plexuses and excising redundant anoderm and mucosa.

Closed Submucosal Hemorrhoidectomy. The Parks or Ferguson hemorrhoidectomy involves resection of hemorrhoidal tissue and closure of the wounds with absorbable suture. The procedure may be performed in the prone or lithotomy position under local, regional, or general anesthesia. The anal canal is examined and an anal speculum inserted. The hemorrhoid cushions and associated redundant mucosa are identified and excised using an elliptical incision starting just distal to the anal verge and extending proximally to the anorectal ring. It is crucial to identify the fibers of the internal sphincter and carefully brush these away from the dissection in order to avoid injury to the sphincter. The apex of the hemorrhoidal plexus is then ligated and the hemorrhoid excised. The wound is then closed with a running absorbable suture. All three hemorrhoidal cushions may
be removed using this technique; however, care should be taken to avoid resecting a large area of perianal skin in order to avoid postoperative anal stenosis (Fig. 29-32).

**Open Hemorrhoidectomy.** This technique, often called the Milligan and Morgan hemorrhoidectomy, follows the same principles of excision described earlier, but the wounds are left open and allowed to heal by secondary intention.

**Whitehead’s Hemorrhoidectomy.** Whitehead’s hemorrhoidectomy involves circumferential excision of the hemorrhoidal cushions just proximal to the dentate line. After excision, the rectal mucosa is then advanced and sutured to the dentate line. While some surgeons still use Whitehead’s hemorrhoidectomy, most have abandoned this approach because of the risk of ectropion (Whitehead’s deformity).

**Procedure for Prolapse and Hemorrhoids/Stapled Hemorrhoidectomy.** Procedure for prolapse and hemorrhoids (PPH) has been proposed as an alternative surgical approach. The term PPH has largely replaced stapled hemorrhoidectomy because the procedure does not involve excision of hemorrhoidal tissue, but instead pexes the redundant mucosa above the dentate line. PPH removes a short circumferential segment of rectal mucosa proximal to the dentate line using a circular stapler. This effectively ligates the venules feeding the hemorrhoidal plexus and fixes redundant mucosa higher in the anal canal. Several studies suggest that this procedure is safe and effective, is associated with less postoperative pain and disability, and has an equivalent risk of postoperative complications when compared to traditional hemorrhoidectomy.97,98 Nevertheless, with increased use of this technique, serious and occasionally life-threatening complications have been described.99

**Doppler-Guided Hemorrhoidal Artery Ligation.** Another recent approach to treating symptomatic hemorrhoids is Doppler-guided hemorrhoidal artery ligation (also called transanal hemorrhoidal dearterioalization). In this procedure, a Doppler probe is used to identify the artery or arteries feeding the hemorrhoidal plexus. These vessels are then ligated. Early reports have shown promise, but long-term durability remains to be determined.100

**Complications of Hemorrhoidectomy.** Postoperative pain following excisional hemorrhoidectomy requires analgesia usually with oral narcotics. Nonsteroidal anti-inflammatory drugs, muscle relaxants, topical analgesics, and comfort measures, including sitz baths, are often useful as well. Urinary retention is a common complication following hemorrhoidectomy and occurs in 10% to 50% of patients. The risk of urinary retention can be minimized by limiting intraoperative and perioperative intravenous fluids and by providing adequate analgesia. Pain can also lead to *fecal impaction*. Risk of impaction may be decreased by preoperative enemas or a limited mechanical bowel preparation, liberal use of laxatives postoperatively, and adequate pain control. While a small amount of *bleeding,* especially with bowel movements, is to be expected, massive hemorrhage can occur after hemorrhoidectomy. Bleeding may occur.
in the immediate postoperative period (often in the recovery room) as a result of inadequate ligation of the vascular pedicle. This type of hemorrhage mandates an urgent return to the operating room where suture ligation of the bleeding vessel will often solve the problem. Bleeding may also occur 7 to 10 days after hemorrhoidectomy when the necrotic mucosa overlying the vascular pedicle sloughs. While some of these patients may be safely observed, others will require an exam under anesthesia to ligate the bleeding vessel or to oversew the wounds if no specific site of bleeding is identified. Infection is uncommon after hemorrhoidectomy; however, necrotizing soft tissue infection can occur with devastating consequences. Severe pain, fever, and urinary retention may be early signs of infection. If infection is suspected, emergent examination under anesthesia, drainage of abscess, and/or débridement of all necrotic tissue are required.

Long-term sequelae of hemorrhoidectomy include incontinence, anal stenosis, and ectropion (Whitehead’s deformity). Many patients experience transient incontinence to flatus, but these symptoms are usually short-lived, and few patients have permanent fecal incontinence. Anal stenosis may result from scarring after extensive resection of perianal skin. Ectropion may occur after Whitehead’s hemorrhoidectomy.

**Anal Fissure**

A fissure in ano is a tear in the anoderm distal to the dentate line. The pathophysiology of anal fissure is thought to be related to trauma from either the passage of hard stool or prolonged diarrhea. A tear in the anoderm causes spasm of the internal anal sphincter, which results in pain, increased tearing, and decreased blood supply to the anoderm. This cycle of pain, spasm, and ischemia contributes to development of a poorly healing wound that becomes a chronic fissure. The vast majority of anal fissures occur in the posterior midline. Ten percent to 15% occur in the anterior midline. Less than 1% of fissures occur off midline.

**Symptoms and Findings.** Anal fissure is extremely common. Characteristic symptoms include tearing pain with defecation and hematochezia (usually described as blood on the toilet paper). Patients may also complain of a sensation of intense and painful anal spasm lasting for several hours after a bowel movement. On physical examination, the fissure can often be seen in the anoderm by gently separating the buttocks. Patients are often too tender to tolerate digital rectal examination, anoscopy, or proctoscopy. An acute fissure is a superficial tear of the distal anoderm and almost always heals with medical management. Chronic fissures develop ulceration and heaped-up edges with the white fibers of the internal anal sphincter visible at the base of the ulcer. There often is an associated external skin tag and/or a hypertrophied anal papilla internally. These fissures are more challenging to treat and may require surgery. A lateral location of a chronic anal fissure may be evidence of an underlying disease such as Crohn’s disease, HIV, syphilis, tuberculosis,
or leukemia. If the diagnosis is in doubt or there is suspicion of another cause for the perianal pain such as abscess or fistula, an examination under anesthesia may be necessary.

**Treatment.** Therapy focuses on breaking the cycle of pain, spasm, and ischemia thought to be responsible for development of fissure in ano. First-line therapy to minimize anal trauma includes bulk agents, stool softeners, and warm sitz baths. The addition of 2% lidocaine jelly or other analgesic creams can provide additional symptomatic relief. Nitroglycerin ointment has been used locally to improve blood flow but often causes severe headaches. Both oral and topical calcium channel blockers (diltiazem and nifedipine) have also been used to heal fissures and may have fewer side effects than topical nitrates.97 Newer agents, such as arginine (a nitric oxide donor) and topical bethanechol (a muscarinic agonist), have also been used to treat fissures. Medical therapy is effective in most acute fissures, but will heal only approximately 50% of chronic fissures.

Botulinum toxin (Botox) causes temporary muscle paralysis by preventing acetylcholine release from presynaptic nerve terminals. Injection of botulinum toxin is used in some centers as an alternative to surgical sphincterotomy for chronic fissure. Although there are few long-term complications from the use of botulinum toxin, healing appears to be equivalent to other medical therapies.98,101 Surgical therapy has traditionally been recommended for chronic fissures that have failed medical therapy, and lateral internal sphincterotomy is the procedure of choice. The aim of this procedure is to decrease spasm of the internal sphincter by dividing a portion of the muscle. Approximately 30% of the internal sphincter fibers are divided laterally by using either an open (Fig. 29-33) or closed (Fig. 29-34) technique. Healing is achieved in more than 95% of patients using this technique,

![Diagram A](image1.png) ![Diagram B](image2.png) ![Diagram C](image3.png) ![Diagram D](image4.png)

**Figure 29-33.** A through D. Open lateral internal sphincterotomy for fissure in ano. m = muscle.

and most patients experience immediate pain relief. Recurrence occurs in less than 10% of patients, and the risk of incontinence (usually to flatus) ranges from 5% to 15%. Advancement flaps (VY) with or without sphincterotomy have also been reported to successfully treat chronic fissures.

**Anorectal Sepsis and Cryptoglandular Abscess Relevant Anatomy.** The majority of anorectal suppurative disease results from infections of the anal glands (cryptoglandular infection) found in the intersphincteric plane. Their ducts traverse the internal sphincter and empty into the anal crypts at the level of the dentate line. Infection of an anal gland results in the formation of an abscess that enlarges and spreads along one of several planes in the perianal and perirectal spaces. The *peri-anal space* surrounds the anus and laterally becomes continuous with the fat of the buttocks. The *intersphincteric space* separates the internal and external anal sphincters. It is continuous with the perianal space distally and extends cephalad into the rectal wall. The *ischiorectal space* is located lateral and posterior to the anus and is bounded medially by the external sphincter, laterally by the ischium, superiorly by the levator ani, and inferiorly by the transverse septum. The ischiorectal space contains the inferior rectal vessels and lymphatics. The two ischiorectal spaces connect posteriorly above the ano-coccygeal ligament but below the levator ani muscle, forming the *deep postanal space*. The *supralevator spaces* lie above the levator ani on either side of the rectum and communicate posteriorly. The anatomy of these spaces influences the location and spread of cryptoglandular infection (Fig. 29-35). As an abscess enlarges, it spreads in one of several directions. A *perianal abscess* is the most common manifestation and appears as a painful swelling at the anal verge. Spread through the external sphincter below the level of the puborectalis produces an *ischiorectal abscess*. These abscesses may become extremely large and may not be visible in the perianal region. Digital rectal exam will reveal a painful swelling laterally in the ischiorectal fossa. *Intersphincteric abscesses* occur in the intersphincteric space and are notoriously difficult to diagnose, often requiring an examination under anesthesia. *Pelvic and supralevator abscesses* are uncommon and may result from extension of an intersphincteric or ischiorectal abscess upward or extension of an intraperitoneal abscess downward (Fig. 29-36).

*Figure 29-35.* Anatomy of perianorectal spaces. (A) Anterior view and (B) lateral view. m = muscle.
**Diagnosis.** Severe anal pain is the most common presenting complaint. A palpable mass is often detected by inspection of the perianal area or by digital rectal examination. Occasionally, patients will present with fever, urinary retention, or life-threatening sepsis. The diagnosis of a perianal or ischiorectal abscess can usually be made with physical exam alone (either in the office or in the operating room). However, complex or atypical presentations may require imaging studies such as CT or MRI to fully delineate the anatomy of the abscess.

**Treatment.** Anorectal abscesses should be treated by drainage as soon as the diagnosis is established. If the diagnosis is in question, an examination and drainage under anesthesia are often the most expeditious ways both to confirm the diagnosis and to treat the problem. Delayed or inadequate treatment may occasionally cause extensive and life-threatening suppuration with massive tissue necrosis and septicemia. Antibiotics are only indicated if there is extensive overlying cellulitis or if the patient is immunocompromised, has diabetes mellitus, or has valvular heart disease. Antibiotics alone are ineffective at treating perianal or perirectal infection.

**Perianal Abscess**
Most perianal abscesses can be drained under local anesthesia in the office, clinic, or emergency room. Larger, more complicated abscesses may require drainage in the operating room. A skin incision is created, and a disk of skin excised to prevent premature closure. No packing is necessary, and sitz baths are started the next day (Fig. 29-37).

**Ischiorectal Abscess**
An ischiorectal abscess causes diffuse swelling in the ischiorectal fossa that may involve one or both sides, forming a “horseshoe” abscess. Simple ischiorectal abscesses are drained through an incision in the overlying skin. Horseshoe abscesses require drainage of the deep postanal space and often require counterincisions over one or both ischiorectal spaces (Fig. 29-38).

**Intersphincteric Abscess**
Intersphincteric abscesses are notoriously difficult to diagnose because they produce little swelling and few perianal signs of infection. Pain is typically described as being deep and “up inside” the anal area and is usually exacerbated by coughing or sneezing. The pain is so intense that it usually precludes a digital rectal examination. The diagnosis is made based on a high index of suspicion and usually requires an examination under anesthesia. Once identified, an intersphincteric abscess can be drained through a limited, usually posterior, internal sphincterotomy.
The immunocompromised patient with perianal pain presents a diagnostic dilemma. Because of leukopenia, these patients may develop serious perianal infection without any of the cardinal signs of inflammation. While broad-spectrum antibiotics may cure some of these patients, an exam under anesthesia should not be delayed because of neutropenia. An increase in pain or clinical deterioration mandates an exam under anesthesia. Any indurated area should be incised and drained, biopsied to exclude a leukemic infiltrate, and cultured to aid in the selection of antimicrobial agents.

**Supralelevator Abscess**

This type of abscess is uncommon and can be difficult to diagnose. Because of its proximity to the peritoneal cavity, supralelevator abscesses can mimic intra-abdominal conditions. Digital rectal examination may reveal an indurated, bulging mass above the anorectal ring. It is essential to identify the origin of a supralelevator abscess prior to treatment. If the abscess is secondary to an upward extension of an intersphincteric abscess, it should be drained through the rectum. If it is drained through the ischiorectal fossa, a complicated, suprasphincteric fistula may result. If a supralelevator abscess arises from the upward extension of an ischiorectal abscess, it should be drained through the ischiorectal fossa. Drainage of this type of abscess through the rectum may result in an extrasphincteric fistula. If the abscess is secondary to intra-abdominal disease, the primary process requires treatment and the abscess is drained via the most direct route (transabdominally, rectally, or through the ischiorectal fossa).

**Perianal Sepsis in the Immunocompromised Patient**

The immunocompromised patient with perianal pain presents a diagnostic dilemma. Because of leukopenia, these patients may develop serious perianal infection without any of the cardinal signs of inflammation. While broad-spectrum antibiotics may cure some of these patients, an exam under anesthesia should not be delayed because of neutropenia. An increase in pain or fever and/or clinical deterioration mandates an exam under anesthesia. Any indurated area should be incised and drained, biopsied to exclude a leukemic infiltrate, and cultured to aid in the selection of antimicrobial agents.

**Necrotizing Soft Tissue Infection of the Perineum**

Necrotizing soft tissue infection of the perineum is a rare, but lethal, condition. Most of these infections are polymicrobial and synergistic. The source of sepsis is commonly an undrained or inadequately drained cryptoglandular abscess or a urogenital infection. Occasionally, these infections may be encountered postoperatively (e.g., after hemorrhoidectomy). Immunocompromised patients and diabetic patients are at increased risk.

Physical examination may reveal necrotic skin, bullae, or crepitus. Patients often have signs of systemic toxicity and may be hemodynamically unstable. A high index of suspicion is necessary because perineal signs of severe infection may be minimal and prompt surgical intervention can be lifesaving.

Surgical débridement of all nonviable tissue is required to treat all necrotizing soft tissue infections. Multiple operations may be necessary to ensure that all necrotic tissue has been resected. Broad-spectrum antibiotics are frequently employed, but adequate surgical débridement remains the mainstay of therapy. Colectomy may be required if extensive resection of the rectum is required or if stool contamination of the perineum makes wound management difficult. Despite early recognition and adequate surgical therapy, the mortality of necrotizing perineal soft tissue infections remains approximately 50%.

**Fistula In Ano**

Drainage of an anorectal abscess results in cure for about 50% of patients. The remaining 50% develop a persistent fistula in ano. The fistula usually originates in the infected crypt (internal opening) and tracks to the external opening, usually the site of prior drainage. The course of the fistula can often be predicted by the anatomy of the previous abscess.

While the majority of fistulas are cryptoglandular in origin, trauma, Crohn’s disease, malignancy, radiation, or unusual infections (tuberculosis, actinomycosis, and chlamydia) may also produce fistulas. A complex, recurrent, or nonhealing fistula should raise the suspicion of one of these diagnoses.

**Diagnosis.** Patients present with persistent drainage from the internal and/or external openings. An indurated tract is often palpable. Although the external opening is often easily identifiable, identification of the internal opening may be more challenging. Goodsell’s rule can be used as a guide in determining the location of the internal opening (Fig. 29-39). In general, fistulas with an external opening anteriorly connect to the internal opening by a short, radial tract. Fistulas with an external opening posteriorly track in a curvilinear fashion to the posterior midline. However, exceptions to this rule often occur if an anterior...
external opening is greater than 3 cm from the anal margin. Such fistulas usually track to the posterior midline.

Fistulas are categorized based on their relationship to the anal sphincter complex, and treatment options are based on these classifications. An intersphincteric fistula tracks through the distal internal sphincter and intersphincteric space to an external opening near the anal verge (Fig. 29-40A). A transsphincteric fistula often results from an ischiorectal abscess and extends through both the internal and external sphincters (Fig. 29-40B). A suprasphincteric fistula originates in the intersphincteric plane and tracks up and around the entire external sphincter (Fig. 29-40C). An extrasphincteric fistula originates in the rectal wall and tracks around both sphincters to exit laterally, usually in the ischiorectal fossa (Fig. 29-40D).

**Treatment.** The goal of treatment of fistula in ano is eradication of sepsis without sacrificing continence. Because fistulous tracks encircle variable amounts of the sphincter complex, surgical treatment is dictated by the location of the internal and external openings and the course of the fistula. The external opening is usually visible as a red elevation of granulation tissue with or without concurrent drainage. The internal opening may be more difficult to identify. Injection of hydrogen peroxide or dilute methylene blue may be helpful. Care must be taken to avoid creating an artificial internal opening (thus often converting a simple fistula into a complex fistula).

Simple intersphincteric fistulas can often be treated by fistulotomy (opening the fistulous tract), curettage, and healing by secondary intention (see Fig. 29-40A). “Horseshoe” fistulas usually have an internal opening in the posterior midline and extend anteriorly and laterally to one or both ischiorectal spaces by way of the deep postanal space. Treatment of a transsphincteric fistula depends on its location in the sphincter complex.

---

**Figure 29-40.** The four major categories of fistula in ano (left side of drawings) and the usual operative procedure to correct the fistula (right side of drawings). A. Intersphincteric fistula with simple low tract. B. Uncomplicated transsphincteric fistula. C. Uncomplicated suprasphincteric fistula. D. Extrasphincteric fistula secondary to anal fistula. (Data from Gordon PH, Nivatvongs S, eds. Principles and Practice of Surgery for the Colon, Rectum, and Anus. 2nd ed. New York: Marcel Dekker, Inc.; 1999:256-250.)
Fistulas that include less than 30% of the sphincter muscles can often be treated by sphincterotomy without significant risk of major incontinence (see Fig. 29-40B). High transsphincteric fistulas, which encircle a greater amount of muscle, are more safely treated by initial placement of a seton (see below). Similarly, suprasphincteric fistulas are usually treated with seton placement (see Fig. 29-40C). Extrasphincteric fistulas are rare, and treatment depends on both the anatomy of the fistula and its etiology. In general, the portion of the fistula outside the sphincter should be opened and drained. A primary tract at the level of the dentate line may also be opened if present. Complex fistulas with multiple tracts may require numerous procedures to control sepsis and facilitate healing. Liberal use of drains and setons is helpful. Failure to heal may ultimately require fecal diversion (see Fig. 29-40D). Complex and/or nonhealing fistulas may result from Crohn’s disease, malignancy, radiation proctitis, or unusual infection. Proctoscopy should be performed in all cases of complex and/or nonhealing fistulas to assess the health of the rectal mucosa. Biopsies of the fistula tract should be taken to rule out malignancy.

A seton is a drain placed through a fistula to maintain drainage and/or induce fibrosis. Cutting setons consist of a suture or a rubber band that is placed through the fistula and intermittently tightened in the office. Tightening the seton results in fibrosis and gradual division of the sphincter, thus eliminating the fistula while maintaining continuity of the sphincter. A noncutting seton is a soft plastic drain (often a vessel loop) placed in the fistula to maintain drainage. The fistula tract may subsequently be laid open with less risk of incontinence because scarving prevents retraction of the sphincter. Alternatively, the seton may be left in place for chronic drainage. Higher fistulas may be treated by an endorectal advancement flap (see below). Fibrin glue and a variety of collagen-based plugs also have been used to treat persistent fistulas with variable results. A more recent technique, ligation of the intersphincteric fistula tract (LIFT), also shows promise. In this procedure, the fistula is identified in the intersphincteric plane (usually by placement of a lacrimal probe), divided, and the two ends ligated. Early reports have shown success with this technique, but long-term outcome is not yet known.103,104

Rectovaginal Fistula

A rectovaginal fistula is a connection between the vagina and the rectum or anal canal proximal to the dentate line. Rectovaginal fistulas are classified as low (rectal opening close to the dentate line and vaginal opening in the fourchette), middle (vaginal opening between the fourchette and cervix), or high (vaginal opening near the cervix). Low rectovaginal fistulas are commonly caused by obstetric injuries or trauma from a foreign body. Mid-rectovaginal fistulas may result from more severe obstetric injury, but also occur after surgical resection of a mid-rectal neoplasm, radiation injury, or extension of an undrained abscess. High rectovaginal fistulas result from operative or radiation injury. Complicated diverticulitis may cause a colovaginal fistula. Crohn’s disease can cause rectovaginal fistulas at all levels, as well as colovaginal and entero vaginal fistulas.

Diagnosis. Patients describe symptoms varying from the sensation of passing flatus from the vagina to the passage of solid stool from the vagina. Most patients experience some degree of fecal incontinence. Contamination may result in vaginitis. Large fistulas may be obvious on anoscopy and/or vaginal speculum examination, but smaller fistulas may be difficult to locate. Occasionally, a barium enema or vaginogram may identify these fistulas. Endorectal ultrasound may also be useful. With the patient in the prone position, installation of methylene blue into the rectum while a tampon is in the vagina may confirm the presence of a small fistula.

Treatment. The treatment of rectovaginal fistula depends on the size, location, etiology, and condition of surrounding tissues. Because up to 50% of fistulas caused by obstetric injury heal spontaneously, it is prudent to wait 3 to 6 months before embarking on surgical repair in these patients. If the fistula was caused by a cryptoglandular abscess, drainage of the abscess may allow spontaneous closure.

Low and mid-rectovaginal fistulas are usually best treated with an endorectal advancement flap. The principle of this procedure is based on the advancement of healthy mucosa, submucosa, and circular muscle over the rectal opening (the high-pressure side of the fistula) to promote healing (Fig. 29-41). If a sphincter injury is present, an overlapping sphincteroplasty should be performed concurrently. Fecal diversion is rarely required. High rectovaginal, colovaginal, and entero vaginal fistulas are usually best treated via a transabdominal approach. The diseased tissue, which caused the fistula (upper rectum, sigmoid colon, or small bowel), is resected and the hole in the vagina closed. Healthy tissue, such as omentum or muscle, frequently is interposed between the bowel anastomosis and the vagina to prevent recurrence.

Rectovaginal fistulas caused by Crohn’s disease, radiation injury, or malignancy almost never heal spontaneously. In Crohn’s disease, treatment is based on adequate drainage of perianal sepsis and nutritional support. An endorectal advancement flap may be performed if the rectum is spared from active Crohn’s disease. Fistulas resulting from radiation damage are not amenable to local repair with an advancement flap because of damage to the surrounding rectal and vaginal tissues. Such mid- and high rectovaginal fistulas are occasionally repaired successfully with a transabdominal approach in which healthy tissue (omentum, muscle, or nonradiated bowel) is interposed between the damaged rectum and vagina. Fistulas caused by malignancy should be treated with resection of the tumor. Because differentiating radiation damage from malignancy can be extremely difficult, all fistulas resulting from radiation should be biopsied to rule out the presence of cancer.

Perianal Dermatitis

Pruritus Ani. Pruritus ani (severe perianal itching) is a common problem with a multitude of etiologies. Surgically correctable (anatomic) causes include prolapsing hemorrhoids, eczephoria, fissure, fistula, and neoplasms. Perianal infection may also present with pruritus ani. Infections may be caused by fungus (Candida species and Epidermophyton organisms), parasites (Enterobius vermicularis [pinworms], Pediculus pubis [a louse], and Sarcoptes scabiei [scabies]), bacteria (Corynebacterium minutissimum [erythrasma] and T. pallidum [syphilis]), or viruses (HPV [condyloma acuminata]). Antibiotic use may also cause itching, usually by precipitating fungal infection.

Noninfectious dermatologic causes include seborrhea, psoriasis, and contact dermatitis. Contact dermatitis can be particularly troublesome because many over-the-counter topical agents used by patients to relieve itching may exacerbate the problem. Occasionally, systemic diseases such as jaundice and diabetes may present with pruritus ani.

Despite the myriad of causes, the majority of pruritus ani is idiopathic and probably related to local hygiene, neurogenic, or...
psychogenic causes. Treatment focuses on removal of irritants, improving perianal hygiene, dietary adjustments, and avoiding scratching. Biopsy and/or culture may be required to rule out an infectious or dermatologic cause. Hydrocortisone ointment 0.5% to 1.0% can provide symptomatic relief but should not be used for prolonged periods of time because of the risk of dermal atrophy. Skin barriers such as Calmoseptine can also provide relief. Systemic antihistamines or tricyclic antidepressants have also been used with some success.

Nonpruritic Lesions. Several perianal skin conditions may present with perianal skin changes. Leprosy, amebiasis, actinomycosis, and lymphogranuloma venereum produce characteristic perianal lesions. Neoplasms such as squamous intraepithelial lesions, Paget’s disease, and invasive carcinomas may also appear first in the perianal skin. Biopsy can usually distinguish these diagnoses.

Sexually Transmitted Diseases

Bacterial Infections. Proctitis is a common symptom of anorectal bacterial infection. *N. gonorrhoeae* is the most common bacterial cause of proctitis and causes pain, tenesmus, rectal bleeding, and mucus discharge. *Chlamydia trachomatis* infection may be asymptomatic or may produce similar symptoms. *T. pallidum*, the microbe causing syphilis, causes a chancre at the site of inoculation, which may be asymptomatic or may present as an atypical fissure (primary syphilis). Condyloma lata are characteristic of secondary syphilis. Chancreoid, caused by *Haemophilus ducreyi*, is a disease manifested by multiple painful, bleeding lesions. Inguinal lymphadenopathy and fluctuant, draining lymph nodes are characteristic. *Donovania granulomatis* infection produces shiny, red masses on the perineum (granuloma inguinale). Diarrheal illnesses caused by organisms such as *Campylobacter* or *Shigella* may also be sexually transmitted.
Treatment consists of antimicrobial agents directed against the infecting organism.

**Parasitic Infections.** *Entamoeba histolytica* is an increasingly common sexually transmitted disease. Amebas produce ulcerations in the gastrointestinal mucosa and can infect any part of the gut. Symptoms include diarrhea, abdominal pain, and tenesmus. *Giardia lambia* is also common and produces diarrhea, abdominal pain, and malaise.

**Viral Infections**

**Herpes Simplex Virus.** Herpes proctitis is extremely common. Proctitis is usually caused by type 2 herpes simplex virus and less commonly by type 1 herpes simplex virus. Patients complain of severe, intractable perianal pain and tenesmus. Pain often precedes the development of characteristic vesicles, and these patients may require an examination under anesthesia to exclude another diagnosis such as an intersphincteric abscess. Diagnosis is confirmed by viral culture of tissue or vesicular fluid.

**Human Papillomavirus.** HPV causes condyloma acuminata (anogenital warts) and is associated with squamous intraepithelial lesions and squamous cell carcinoma (see previous section, “Anal Canal and Perianal Tumors”). Condylomas occur in the perianal area or in the squamous epithelium of the anal canal. Occasionally, the mucosa of the lower rectum may be affected. There are approximately 30 serotypes of HPV. As previously mentioned, HPV types 16 and 18, in particular, appear to predispose to malignancy and often cause flat dysplasia in skin unaffected by warts. In contrast, HPV types 6 and 11 commonly cause warts, but do not appear to cause malignant degeneration.

Treatment of anal condyloma depends on the location and extent of disease. Small warts on the perianal skin and distal anal canal may be treated in the office with topical application of bichloracetic acid or podophyllin. Although 60% to 80% of patients will respond to these agents, recurrence and reinfection are common. Imiquimod (Aldara) is an immunomodulator that was recently introduced for topical treatment of several viral infections, including anogenital condyloma. Initial reports suggest that this agent is highly effective in treating condyloma located on the perianal skin and distal anal canal. Larger and/or more numerous warts require excision and/or fulguration in the operating room. Excised warts should be sent for pathologic examination to rule out dysplasia or malignancy. It is important to note that prior use of podophyllin may induce histologic changes that mimic dysplasia. The recent introduction of a vaccine against HPV holds promise for preventing anogenital condylomas.

**Human Immunodeficiency Virus.** See later section, “The Immunocompromised Patient.”

**Pilonidal Disease**

Pilonidal disease (cyst, infection) consists of a hair-containing sinus or abscess occurring in the intergluteal cleft. Although the etiology is unknown, it is speculated that the cleft creates a suction that draws hair into the midline pits when a patient sits. These ingrown hairs may then become infected and present acutely as an abscess in the sacrococcygeal region. Once an acute episode has resolved, recurrence is common.

An acute abscess should be incised and drained as soon as the diagnosis is made. Because these abscesses are usually very superficial, this procedure can often be performed in the office, clinic, or emergency room under local anesthetic. Because midline wounds in the region heal poorly, some surgeons recommend using an incision lateral to the intergluteal cleft. A number of procedures have been proposed to treat a chronic pilonidal sinus. The simplest method involves unroofing the tract, curetting the base, and marsupializing the wound. The wound must then be kept clean and free of hair until healing is complete (often requiring weekly office visits for wound care). Alternatively, a small lateral incision can be created and the pit excised. This method is effective for most primary pilonidal sinuses. In general, extensive resection should be avoided. Complex and/or recurrent sinus tracts may require more extensive resection and closure with a Z-plasty, advancement flap, or rotational flap.

**Hidradenitis Suppurativa**

Hidradenitis suppurativa is an infection of the cutaneous apocrine sweat glands. Infected glands rupture and form subcutaneous sinus tracts. The infection may mimic complex anal fistula disease, but stops at the anal verge because there are no apocrine glands in the anal canal. Treatment involves incision and drainage of acute abscesses and unroofing of all chronically inflamed fistulas and debridement of granulation tissue. Radical excision and skin grafting are almost never necessary.

**TRAUMA**

**Penetrating Colorectal Injury**

Colorectal injury is common following penetrating trauma to the abdomen and has historically been associated with high mortality. In the first half of the twentieth century, the mortality rate from colorectal injury was as high as 90%. The introduction of exteriorization of colonic injuries and fecal diversion during World War II dramatically decreased mortality, and this principle has governed the management of large bowel injury for over 50 years. Recently, however, this practice was challenged, and trauma surgeons are increasingly performing primary repairs in selected patients.

Management of colonic injury depends on the mechanism of injury, the delay between the injury and surgery, the overall condition and stability of the patient, the degree of peritoneal contamination, and the condition of the injured colon. A primary repair may be considered in hemodynamically stable patients with few additional injuries and minimal contamination if the colon appears otherwise healthy. Contraindications to primary repair include shock, injury to more than two other organs, mesenteric vascular damage, and extensive fecal contamination. A delay of greater than 6 hours between the injury and the operation also is associated with increased morbidity and mortality and is a relative contraindication to primary repair. Injuries caused by high-velocity gunshot wounds or blast injuries are often associated with multiple intra-abdominal injuries and tissue loss and therefore are usually treated by fecal diversion after debridement of all nonviable tissue. Patient factors, such as medical comorbidities, advanced age, and the presence of tumor or radiation injury, must also be considered (Table 29-6).

Like injuries to the intraperitoneal colon, penetrating trauma to the rectum traditionally has been associated with high morbidity and mortality. Primary repair of the rectum is more difficult than primary repair of the colon, however, and most rectal injuries are associated with significant contamination. For that reason, the majority of penetrating rectal injuries should be treated with proximal fecal diversion and copious irrigation of
Injury factors
- Inflamed tissue
- Advanced infection
- Distal obstruction
- Local foreign body
- Impaired blood supply
- Mesenteric vascular damage
- Shock with blood pressure <80/60 mmHg
- Hemorrhage >1000 mL
- More than two organs (especially kidney) injured

Interval to operation >6 h (pancreatic, splenic, hepatic)
- Extensive injury requiring resection
- Major abdominal wall loss
- Thoracoabdominal penetration

In a completely asymptomatic patient, this finding is thought to result from barotrauma and dissection of air through tissue planes without a free perforation. Many of these patients can be successfully treated with bowel rest and broad-spectrum antibiotics. Surgical exploration is indicated if any clinical deterioration occurs.

**Anal Sphincter Injury and Incontinence**

The most common cause of anal sphincter injury is obstetric trauma during vaginal delivery. The risk of sphincter injury is increased by a laceration that extends into the rectum (fourth-degree tear), infection of an episiotomy or laceration repair, prolonged labor, and possibly by use of a midline episiotomy. Sphincter damage may also result from hemorrhoidectomy, sphincterotomy, abscess drainage, or fistulotomy. Patients with incontinence and a suspected sphincter injury can be evaluated with anal manometry, EMG, pudendal nerve motor latency, and endoanal ultrasound. Mild incontinence, even in the presence of a sphincter defect, may respond to dietary changes and/or biofeedback. More severe incontinence may require surgical repair.

The anal sphincter can also be injured by penetrating or blunt mechanisms (impalement, blast injury, crush injuries of the pelvis). Because damage to the anal sphincter is not life-threatening, definitive repair of the sphincter is often deferred until other injuries have been repaired and the patient’s clinical condition is stable. Isolated sphincter injuries that do not involve the rectum may be repaired primarily. Rectal injury accompanied by sphincter injury should be treated with fecal diversion and distal rectal washout, with or without drain placement. Significant perineal tissue loss may require extensive debridement and a diverting colostomy.

**Surgical Repairs.** The most common method of repair of the anal sphincter is a wrap-around sphincteroplasty (Fig. 29-42).\(^\text{106}\) The procedure involves mobilization of the divided sphincter muscle and reapproximation without tension. The internal and external sphincters may be overlapped together or separately. Postanal intersphincteric levatorplasty is less commonly used to repair sphincter defects but may be useful for incontinence caused by prolapse and/or loss of the anorectal angle (see “Continence”). The approach is via the intersphincteric plane posteriorly. It may be performed concomitantly with a perineal repair of rectal prolapse. The levator ani muscle is approximated to restore the anorectal angle, and the puborectalis and external sphincter muscle are tightened with sutures. These elective procedures usually do not require a diverting colostomy.

In cases where there has been significant loss of sphincter muscle or in which prior repairs have failed, more complex techniques, such as gracilis muscle transposition \(^\text{105}\) in this procedure, the gracilis muscle is mobilized from the thigh, detached from its insertion on the tibial tuberosity, tunneled through the perineum, and wrapped around the anal canal. Another alternative in patients who have failed other repairs is the artificial anal sphincter. This device consists of an inflatable silastic cuff, a pressure-regulating balloon, and a control pump. Patients deflate the cuff manually to open the anal canal; the cuff then reinflates spontaneously to maintain closure of the anal canal. Sacral nerve stimulation via an implanted pulse generator is a technique used for neurogenic incontinence when the sphincter is intact.\(^\text{16,27}\) In some patients, an end stoma provides the best relief for intractable incontinence.\(^\text{101}\)

---

**Figure 29-42.** Overlapping sphincteroplasty for incontinence from sphincter disruption. A. The external sphincter muscle with scar at site of injury is mobilized. B. The muscle edges are aligned in an overlapping fashion. C. Mattress sutures are used to approximate the muscle. D. The completed operation.

---

**Foreign Body**

Foreign body entrapment in the rectum is not uncommon. Depending on the level of entrapment, a foreign body may cause damage to the rectum, rectosigmoid, or descending colon. Generalized abdominal pain suggests intraperitoneal perforation. Evaluation of the patient includes inspection of the perineum and a careful abdominal examination to detect any evidence of perforation. Plain films of the abdomen are mandatory to detect free intra-abdominal air.

Foreign bodies lodged low in the rectum may often be removed under conscious sedation with or without a local anesthetic block. Objects impacted higher in the rectum may require regional or general anesthesia for removal. Only rarely will a laparotomy be required to remove the object. After removal of the foreign body, it is crucial to evaluate the rectum and sigmoid colon for injury. Proctoscopy and/or flexible sigmoidoscopy should be performed. A hematoma without evidence of perforation requires no surgical treatment. Perforation of the rectum or sigmoid colon should be managed as described in the preceding sections.

---

**THE IMMUNOCOMPROMISED PATIENT**

**Human Immunodeficiency Virus**

Patients infected with HIV may present with a myriad of gastrointestinal symptoms. Diarrhea, in particular, is extremely common. The severity of gastrointestinal disease depends
in part on the degree of immunosuppression; however, both ordinary and opportunistic pathogens may affect patients at any stage of the disease. Opportunistic infections with bacteria (Salmonella, Shigella, Campylobacter, Chlamydia, and Mycobacterium species), fungi (histoplasmosis, coccidiosis, Cryptococcus), protozoa (toxoplasmosis, cryptosporidiosis, isosporiasis), and viruses (CMV, herpes simplex virus) can cause diarrhea, abdominal pain, and weight loss. CMV in particular may cause severe enterocolitis and is the most common infectious cause of emergency laparotomy in acquired immunodeficiency syndrome (AIDS) patients. C. difficile colitis is a major concern in these patients, especially because many patients are maintained on suppressive antibiotic therapy. The incidence of gastrointestinal malignancy is also increased in patients with HIV infection. Kaposi’s sarcoma is the most common malignancy in AIDS patients and can affect any part of the gastrointestinal tract. Patients may be asymptomatic or may develop bleeding or obstruction. Gastrointestinal lymphoma (usually non-Hodgkin’s lymphoma) is also common. The incidence of colorectal carcinoma may also be increased in this population, although definitive data are lacking.

Perianal disease is extremely common in patients with HIV infection. Because HIV is sexually transmitted, it is common to find concomitant infection with other sexually transmitted diseases such as Chlamydia, herpes simplex virus, and HPV (anal condyloma). Anal condyloma in particular are very common, and the incidence of dysplasia (HSIL) is high in the HIV-infected population. Abscesses and fistulas may be more difficult to diagnose in these patients and may be complex. Many patients require an examination under anesthesia with biopsy and cultures to determine the etiology of many of these perianal problems. The introduction of highly active antiretroviral therapy (HAART) has changed the natural history of HIV infection, but it remains to be seen how these medications will affect the incidence and outcome of colorectal disease in this patient population.

IMMUNOSUPPRESSION FOR TRANSPLANTATION

The gastrointestinal tract is a common site for posttransplantation complications that are responsible for significant morbidity and mortality. In these patients, infection and medication are the most common causes of diarrhea. Immunosuppressant medications, in particular, may cause diarrhea. CMV infection is common and may be severe. C. difficile colitis also occurs commonly. Diverticulitis appears to be more common in some populations of transplant patients and may be more likely to present with abscess or free perforation. Elective resection after recovery from one episode of confirmed diverticulitis may be indicated in the transplant population. Graft-versus-host disease is unique to transplant patients and often requires endoscopy and biopsy to diagnose gastrointestinal involvement. Patients are subject to the same opportunistic infections outlined earlier; however, sexually transmitted infections and Kaposi’s sarcoma are somewhat less prevalent. Perianal disease is somewhat less common in the transplant population than in patients infected with HIV; however, similar infections may occur, and immunosuppression often makes diagnosis and treatment challenging.

With increasing long-term survival among transplant recipients, the development of posttransplant malignancy has become a major concern. Posttransplant lymphoproliferative disease is increasingly common and may occur anywhere in the gastrointestinal tract. The risk of colorectal carcinoma is increased in patients with predisposing conditions such as ulcerative colitis. However, immunosuppression alone does not appear to increase the incidence of colorectal cancer, and current screening recommendations are similar to those for the average risk population. In contrast, the incidence of anal squamous cell carcinoma is dramatically increased in transplant patients, and patients with known HPV infection should undergo more vigorous screening.

THE NEUTROPENIC PATIENT

Neutropenic enterocolitis (typhlitis) is a life-threatening problem with a mortality rate of greater than 50%. This syndrome is characterized by abdominal pain and distention, fever, diarrhea (often bloody), nausea, and vomiting in a patient with fewer than 1000 neutrophils/μL blood from any cause (bone marrow transplantation, solid-organ transplantation, or chemotherapy). CT scan of the abdomen often shows a dilated cecum with pericolic stranding. However, a normal-appearing CT scan does not exclude the diagnosis. Some patients will respond to bowel rest, broad-spectrum antibiotics, parenteral nutrition, and granulocyte infusion or colony-stimulating factors. Evidence of perforation, generalized peritonitis, and deterioration in clinical condition are indications for operation.

Neutropenic patients often develop perianal pain, and diagnosis may be difficult because of a lack of inflammatory response to infection. While broad-spectrum antibiotics may cure some of these patients, an examination under anesthesia should not be delayed because of neutropenia. An increase in pain or fever and/or clinical deterioration mandates an exam under anesthesia. Any indurated area should be incised and drained, biopsied to exclude a leukemic infiltrate, and cultured to aid in the selection of antimicrobial agents.

REFERENCES

Entries highlighted in bright blue are key references.

Appendicular disease is a frequent reason for emergency hospital admission, and appendectomy is one of the most common emergency procedures performed in contemporary medicine. Despite the prevalent role this organ plays in healthcare today, the human appendix was not noted until 1492. Leonardo da Vinci depicted the appendix in his anatomic drawings, but these were not published until the eighteenth century.

In 1521, Berengario Da Capri and, in 1543, Andreas Vesalius published drawings recognizing the appendix.

Credit is given to Jean Fernel for first describing appendicular disease in a paper published in 1544. He reported on a 7-year-old girl whose diarrhea he treated with doses of quince, an apple-like fruit used in folk remedies. She developed abdominal pain and died. At autopsy, the quince was found to have obstructed the lumen of the appendix, causing necrosis and perforation.

Lorenz Heister provided the first description of classic appendicitis in 1711.

The first known appendectomy was performed in 1736 by Claudius Amyand in London. He operated on an 11-year-old boy with a scrotal hernia and a fecal fistula. Within the hernia sac, Amyand found a perforated appendix surrounded by omentum. The appendix and omentum were amputated. The patient was discharged a month later in good condition.

It would be over a century later before appendicitis was widely recognized as a common cause of right lower quadrant pain and early appendectomy advocated as treatment. Throughout this period, there was extensive discussion of typhilitis and perityphlitis as the common etiologies of right lower quadrant pain. Only sporadic cases of right lower quadrant pain were treated with appendectomy. In 1886, Reginald H. Fitz presented his findings regarding appendicitis and recommended consideration for operative treatment. In 1889, Charles McBurney published his landmark paper in the New York State Medical Journal describing the indications for early laparotomy for the treatment of appendicitis. During the following decade, the role of surgical treatment was discussed intensely between proponents of early appendectomy and of a more expectant management. It was recognized that most instances of appendicitis could resolve without surgical treatment; but, the problem was how to identify early the patients who had the progressive, often lethal form of the disease.

Eventually, early appendectomy became the accepted standard of care, with broad indications in order to prevent perforation. This change in practice resulted in an enormous increase in the number of appendectomies during the first decades of the twentieth century. However, this had almost no impact on the incidence of perforated appendicitis or on the mortality of appendicitis.

In the 1970s, the negative effects of the large number of appendectomies of uninflamed appendices were noted, and the focus gradually shifted toward a more conservative approach to exploration.

**EMBRYOLOGY, ANATOMY, AND PHYSIOLOGY**

**Embryology**

In the sixth week of human embryonic development, the appendix and cecum appear as outpouchings from the caudal limb of the midgut. The appendiceal outpouching, initially noted in the eighth week, begins to elongate at about the fifth month to achieve a vermiform appearance. The appendix maintains...
Appendicitis is one of the most common surgical emergencies in contemporary medicine, with a yearly incidence rate of about 100 per 100,000 inhabitants. Lifetime risk for appendicitis is 8.6% for males and 6.7% for females, with the highest incidence in the second decade of life.

The natural history of appendicitis is unclear, but it appears that progression to perforation is not predictable and that spontaneous resolution is common, suggesting that nonperforated and perforated appendicitis may, in fact, be different diseases.

Right lower quadrant pain, gastrointestinal symptoms starting after the onset of pain, and a systemic inflammatory response with leukocytosis and neutrophilia, increased C-reactive protein concentration, and fever are considered diagnostic of appendicitis. The Appendicitis Inflammatory Response Score or Alvarado score can help improve diagnostic accuracy.

Computed tomography scan has improved diagnostic accuracy in individual studies. However, in population-wide studies, the rate of misdiagnosis of appendicitis remains constant. Rates of misdiagnosis are highest in female patients of child-bearing age and patients on the extremes of age (i.e., very young and very old).

The role of nonoperative treatment for uncomplicated appendicitis remains controversial. Currently, appendectomy remains the standard of care. Laparoscopic appendectomy has a slight benefit over open appendectomy.

Perforated or complicated appendicitis is more common in the very young (age <3 years) and very old (age >65 years).

Complicated appendicitis without signs of sepsis or generalized peritonitis may benefit from nonoperative management. The role of interval appendectomy in these cases remains controversial.

Single-incision appendectomy provides no obvious advantage over standard laparoscopic appendectomy. Natural orifice transluminal endoscopic surgery remains an investigational procedure.

The incidence of fetal loss following normal appendectomy in pregnant patients is 4%, and the risk of premature delivery is 10%. The greatest opportunity to improve fetal outcomes may be through improving diagnostic accuracy and reducing the rate of negative appendectomy.

Antibiotic prophylaxis is effective in the prevention of postoperative surgical site infection. Postoperative antibiotics are unnecessary following uncomplicated appendicitis. For complicated appendicitis, a treatment duration of 4 to 7 days is recommended.

The role of incidental appendectomy is limited to patients at high risk for misdiagnosis of appendicitis (malrotation, patients unable to respond or react normally), patients at high risk for complications with appendicitis (children ready to undergo chemotherapy), and patients with limited access to modern healthcare.

The prevalence of appendiceal malignancy remains at or below 1% of appendectomies. Carcinoid and mucinous adenocarcinoma remain the most frequent histologic diagnosis.

its position at the tip of the cecum throughout development. The subsequent unequal growth of the lateral wall of the cecum causes the appendix to find its adult position on the posterior medial wall, just below the ileocecal valve. The base of the appendix can be located by following the longitudinally oriented taeniae coli to their confluence on the cecum. The tip of the appendix can be located anywhere in the right lower quadrant of the abdomen, pelvis, or retroperitoneum.

In patients with midgut malrotation and situs inversus, the cecum (and thus the appendix) will not reside in the usual right lower quadrant location. With midgut malrotation, the midgut (small bowel and proximal colon) incompletely rotates or fails to rotate around the axis of the superior mesenteric artery during fetal development. In this situation, the appendix will remain in the left upper quadrant of the abdomen. Situs inversus is a rare autosomal recessive congenital defect characterized by the transposition of abdominal and/or thoracic organs. In this situation, the appendix is found in the left lower quadrant of the abdomen.

Anatomy

In the adult, the average length of the appendix is 6 to 9 cm; however, it can vary in length from <1 to >30 cm. The outer diameter varies between 3 and 8 mm, whereas the luminal diameter varies between 1 and 3 mm.

The appendix receives its arterial supply from the appendicular branch of the ileocolic artery. This artery originates posterior to the terminal ileum, entering the mesoappendix close to the base of the appendix. The lymphatic drainage of the appendix flows into lymph nodes that lie along the ileocolic artery. Innervation of the appendix is derived from sympathetic elements contributed by the superior mesenteric plexus (T10-L1) and afferents from the parasympathetic elements via the vagus nerves.

The histologic features of the appendix are contained within the three following layers: the outer serosa, which is an extension of the peritoneum; the muscularis layer, which is not well defined and may be absent in certain locations; and finally, the submucosa and mucosa. Lymphoid aggregates occur in the submucosal layer and may extend into the muscularis mucosa. Lymphatic channels are prominent in regions underlying these lymphoid aggregates. The mucosa is like that of the large intestine, except for the density of the lymphoid follicles. The crypts are irregularly sized and shaped, in contrast to the more uniform appearance of the crypts in the colon. Neuroendocrine complexes composed of ganglion cells, Schwann cells, neural fibers, and neurosecretory cells are positioned just below the crypts.

Physiology

For many years, the appendix was erroneously believed to be a vestigial organ with no known function. It is now well recognized that the appendix is an immunologic organ that actively participates in the secretion of immunoglobulins, particularly immunoglobulin A.
Although there is no clear role for the appendix in the development of human disease, an inverse association between appendectomy and the development of ulcerative colitis has been reported, suggesting a protecting effect of the appendectomy. However, this association is only seen in patients treated with appendectomy for appendicitis before age 20.12-27

The association between Crohn’s disease and appendectomy is less clear. Although earlier studies suggested that appendectomy increases the risk of developing Crohn’s disease, more recent studies that carefully assessed the timing of appendectomy in relationship to the onset of Crohn’s disease demonstrated no correlation.17 A recent meta-analysis demonstrated a significant risk of Crohn’s disease early following appendicitis.18 This risk diminishes later, which suggests that a diagnostic (misidentifying Crohn’s disease as appendicitis) rather than a physiologic relationship exists between appendectomy and Crohn’s disease.

The appendix may function as a reservoir to recolonize the colon with healthy bacteria. One retrospective study demonstrated that prior appendectomy may have an inverse relationship to recurrent Clostridium difficile infections.19 However, in another retrospective study, prior appendectomy did not affect the rate of C. difficile infections.20 The role of the appendix in recolonizing the colon remains to be elucidated.

ACUTE APPENDICITIS

Epidemiology

The lifetime risk of developing appendicitis is 8.6% for males and 6.7% for females, with the highest incidence in the second and third decades.21 The rate of appendectomy for appendicitis has been decreasing since the 1950s in most countries. In the United States, it reached its lowest incidence rate of about 15 per 10,000 inhabitants in the 1990s.22 Since then, there has been an increase in the incidence rate of nonperforated appendicitis. The reason for this is not clear, but it has been proposed that the increased use of diagnostic imaging has led to a higher detection rate of mild appendicitis that would otherwise resolve undetected.

Etiology and Pathogenesis

The etiology and pathogenesis of appendicitis are not completely understood. Obstruction of the lumen due to fecoliths or hypertrophy of lymphoid tissue is proposed as the main etiologic factor in acute appendicitis. The frequency of obstruction rises with the severity of the inflammatory process. Fecoliths and calculi are found in 40% of cases of simple acute appendicitis,23 in 65% of cases of gangrenous appendicitis without rupture, and in nearly 90% of cases of gangrenous appendicitis with rupture.24

Traditionally, the belief has been that there is a predictable sequence of events leading to eventual appendiceal rupture. The proximal obstruction of the appendiceal lumen produces a closed-loop obstruction, and continuing normal secretion by the appendiceal mucosa rapidly produces distension. Distension of the appendix stimulates the nerve endings of visceral afferent stretch fibers, producing vague, dull, diffuse pain in the mid-abdomen or lower epigastrium. Distension increases from continued mucosal secretion and from rapid multiplication of the resident bacteria of the appendix. This causes reflex nausea and vomiting, and the visceral pain increases. As pressure in the organ increases, venous pressure is exceeded. Capillaries and venules are occluded but arterial inflow continues, resulting in engorgement and vascular congestion. The inflammatory process soon involves the serosa of the appendix and in turn the parietal peritoneum. This produces the characteristic shift in pain to the right lower quadrant.

The mucosa of the appendix is susceptible to impairment of blood supply; thus, its integrity is compromised early in the process, which allows bacterial invasion. The area with the poorest blood supply suffers the most: ellipsoidal infarcts develop in the antimesenteric border. As distension, bacterial invasion, compromise of the vascular supply, and infarction progress, perforation occurs, usually on the antimesenteric border just beyond the point of obstruction. This sequence is not inevitable, however, and some episodes of acute appendicitis may resolve spontaneously.

Microbiology

Appendicitis may occur in clusters, suggesting an infectious genesis. However, an association with various contagious bacteria and viruses has only been found in a small proportion of appendicitis patients.25 The flora of the inflamed appendix differs from that of the normal appendix. About 60% of aspirates of inflamed appendices have anaerobes compared to 25% of aspirates from normal appendices.26 Tissue specimens from the inflamed appendix wall (not luminal aspirates) virtually all grow Escherichia coli and Bacteroides species on culture.27,28 Fusobacterium nucleatum/helicobacterium, which is not present in the normal cecal flora, has been identified in 62% of inflamed appendices.29 In addition to the other usual species (Peptostreptococcus, Pseudomonas, Bacteroides fragilis, Bacteroides intermedius, Lactobacillus), previously unreported fastidious gram-negative anaerobic bacilli have been encountered. Patients with gangrene or perforated appendicitis appear to have more tissue invasion by Bacteroides.

Natural History

Because of the current predilection for surgical treatment, the natural history of appendicitis has not been well described. An increasing amount of circumstantial evidence suggests that not all patients with appendicitis will progress to perforation and that resolution may be a common event.30 Among the strongest evidence are two randomized trials comparing early laparoscopy with conservative management of patients with acute abdominal pain. These studies found three to five times more patients with appendicitis in the group of patients who were randomized to laparoscopy.31,32 Based on epidemiologic differences, it has been proposed that nonperforated and perforated appendicitis may, in fact, be different diseases.22

Clinical Presentation

The inflammatory process in the appendix presents as pain, which initially is of a diffuse visceral type and later becomes more localized as the peritoneal lining gets irritated (Table 30-1).33

Symptoms. Appendicitis usually starts with periumbilical and diffuse pain that eventually localizes to the right lower quadrant (sensitivity, 81%; specificity, 53%).34 Although right lower quadrant pain is one of the most sensitive signs of appendicitis, pain in an atypical location or minimal pain will often be the initial presentation. Variations in the anatomic location of the appendix may account for the differing presentations of the somatic phase of pain.

Appendicitis is also associated with gastrointestinal symptoms like nausea (sensitivity, 58%; specificity, 36%), vomiting (sensitivity, 51%; specificity, 45%), and anorexia (sensitivity,

Conclusions: Individually, disease history, clinical findings, and laboratory tests are weak. But, when combined, they yield high discriminatory power.

68%; specificity, 36%). Gastrointestinal symptoms that develop before the onset of pain suggest a different etiology such as gastroenteritis.\textsuperscript{33} Many patients complain of a sensation of obstruction prior to the onset of pain and feel that defecation will relieve their abdominal pain. Diarrhea may occur in association with perforation, especially in children.

**Signs.** Early in presentation, vital signs may be minimally altered. The body temperature and pulse rate may be normal or slightly elevated. Changes of greater magnitude may indicate that a complication has occurred or that another diagnosis should be considered.\textsuperscript{35}

Physical findings are determined by the presence of peritoneal irritation and are influenced by whether the organ has already ruptured when the patient is first examined. Patients with appendicitis usually move slowly and prefer to lie supine due to the peritoneal irritation. On abdominal palpation, there is tenderness with a maximum at or near McBurney’s point (Fig. 30-1).\textsuperscript{3} On deep palpation, one can often feel a muscular resistance (guarding) in the right iliac fossa, which may be more evident when compared to the left side. When the pressure of the examining hand is quickly relieved, the patient feels a sudden pain, the so-called rebound tenderness. Indirect tenderness (Rovsing’s sign) and indirect rebound tenderness (i.e., pain in the right lower quadrant when the left lower quadrant is palpated) are strong indicators of peritoneal irritation. Rebound tenderness can be very sharp and uncomfortable for the patient. It is therefore recommended to start with testing for indirect rebound tenderness and direct percussion tenderness.

Anatomic variations in the position of the inflamed appendix lead to deviations in the usual physical findings. With a retrocecal appendix, the abdominal findings are less striking, and tenderness may be most marked in the flank. When the appendix hangs into the pelvis, abdominal findings may be entirely absent, and the diagnosis may be missed. Right-sided rectal tenderness is said to help in this situation, but the diagnostic value is low. Pain with extension of the right leg (psoas sign) indicates a focus of irritation in the proximity of the right psoas muscle. Similarly, stretching of the obturator internus through internal rotation of a flexed thigh (obturator sign) suggests inflammation near the muscle.

**Laboratory Findings.** Appendicitis is associated with an inflammatory response that is strongly related to the severity of
the disease. Laboratory examinations are therefore an important part of the diagnosis. Mild leukocytosis is often present in patients with acute, uncomplicated appendicitis and is usually accompanied by a polymorphonuclear prominence. It is unusual for the white blood cell count to be \( >18,000 \text{ cells/mm}^3 \) in uncomplicated appendicitis. Counts above this level raise the possibility of a perforated appendix with or without an abscess. An increased C-reactive protein (CRP) concentration is a strong indicator of appendicitis, especially for complicated appendicitis.

White blood cell counts can be low due to lymphopenia or septic reaction, but in this situation, the proportion of neutrophils is usually very high. Therefore, all inflammatory variables should be viewed together. Appendicitis is very unlikely if the white blood cell count, proportion of neutrophils, and CRP are all normal. The inflammatory response in acute appendicitis is a dynamic process. Early in the process, the inflammatory response can be weak. CRP elevation, in particular, can have up to a 12-hour delay. A decreasing inflammatory response may indicate spontaneous resolution.

Urinalysis can be useful to rule out the urinary tract as the source of infection; however, several white or red blood cells can be present from irritation of the ureter or bladder. Bacteriuria is generally not seen.

**Clinical Scoring Systems.** The clinical diagnosis of appendicitis is a subjective estimate of the probability of appendicitis based on multiple variables that individually are weak discriminators; however, used in conjunction, they possess a high predictive value. This process can be made more objective by the use of clinical scoring systems, which are based on variables with proven discriminating power and assigned a proper weight. The Alvarado score is the most widespread scoring system. It is especially useful for ruling out appendicitis and selecting patients for further diagnostic workup.

![Figure 30-1. McBurney’s point (1 = anterior superior iliac spine; 2 = umbilicus; x = McBurney’s point).](image)

**Imaging Studies.** Plain films of the abdomen can show the presence of a fecolith and fecal loading in the cecum associated with appendicitis but are rarely helpful in diagnosing acute appendicitis; however, they may be of benefit in ruling out other pathology. A chest radiograph is helpful to rule out referred pain from a right lower lobe pneumonic process. If the appendix fills on barium enema, appendicitis is unlikely; however, this test is not indicated in the acute setting. Technetium-99m-labeled

Score: <3: Low likelihood of appendicitis  
4–6: Consider further imaging  
≥7: High likelihood of appendicitis  

Score: 0–4: Low probability. Outpatient follow-up.  
5–8: Indeterminate group. Active observation or diagnostic laparoscopy.  
leukocyte scan has been reported for use in diagnosing appendicitis with good results but has not gained widespread use due to its relative unavailability and impracticality in daily use.\textsuperscript{45}

Ultrasoundography and computed tomography (CT) scan are the most commonly used imaging tests in patients with abdominal pain, particularly in evaluation of possible appendicitis. Multiple meta-analyses have been performed comparing the two imaging modalities (Table 30-3).\textsuperscript{46-47} Overall, CT scan is more sensitive and specific than ultrasoundography in diagnosing appendicitis.

Graded compression ultrasonography is inexpensive, can be performed rapidly, does not require a contrast medium, and can be used in pregnant patients. Sonographically, the appendix is identified as a blind-ending, nonperistaltic bowel loop originating from the cecum. With maximal compression, the diameter of the appendix is measured in the anterior-posterior direction. Thickening of the appendiceal wall and the presence of periappendiceal fluid are highly suggestive of appendicitis. Demonstration of an easily compressible appendix measuring <5 mm in diameter excludes the diagnosis of appendicitis. The sonographic diagnosis of acute appendicitis has a reported sensitivity of 55% to 96% and a specificity of 85% to 98%. Ultrasoundography is similarly effective in children and pregnant women, although its application is limited in late pregnancy. Ultrasoundography has its limitations, particularly the operator-dependent nature of results. In the adult population, ultrasonography remains limited in its use.

With high-resolution helical CT, the inflamed appendix appears dilated (>5 mm), and the wall is thickened. There is often evidence of inflammation, which can include periappendiceal fat stranding, thickened mesoappendix, periappendiceal phlegmon, and free fluid. Fecaliths can be often visualized; however, their presence is not pathognomonic of appendicitis. CT scanning is also an excellent technique for identifying other inflammatory processes masquerading as appendicitis. Several CT techniques have been used, including focused and nonfocused CT scans and contrast and noncontrast scans. Surprisingly, all of these techniques have yielded essentially identical rates of diagnostic accuracy: 92% to 97% sensitivity, 85% to 94% specificity, 90% to 98% accuracy, 75% to 95% positive predictive value, and 95% to 99% negative predictive value. The additional use of rectal contrast does not improve the results of CT scanning.

A number of studies have documented improvement in diagnostic accuracy with the liberal use of CT scanning in the workup of suspected appendicitis. CT lowered the rate of negative appendectomies from 19% to 12% in one study\textsuperscript{48} and the incidence of negative appendectomies in women from 24% to 5% in another study.\textsuperscript{49} Use of CT altered the care of 24% of patients studied and provided an alternative diagnosis in half of the patients with normal appendices on CT scan.

Despite the potential usefulness of CT, there are significant disadvantages. CT scanning is expensive, exposes the patient to significant radiation, and has limited use during pregnancy. Allergy to iodine or contrast limits the administration of contrast agents in some patients, and others cannot tolerate the oral ingestion of luminal dye.

The role of CT scanning in patients who present with right lower quadrant pain is unclear. One rationale is universal CT scanning. There is, however, an argument that indiscriminate diagnostic imaging can increase the detection of clinically nonsignificant appendicitis that would resolve without treatment. Alternatively, selective CT scanning based on the likelihood of appendicitis takes advantage of the clinical skills of the surgeon and, when indicated, adds the expertise of the radiologist.

Despite the increased use of ultrasonography and CT, the rate of misdiagnosis of appendicitis has remained constant (15%). The percentage of misdiagnosed cases of appendicitis is significantly higher among women than men (22% vs. 9.3%). The negative appendectomy rate is highest in women of reproductive age.

**Differential Diagnosis**

The differential diagnosis of acute appendicitis is essentially the diagnosis of acute abdomen. An identical clinical picture can result from a wide variety of acute processes within the peritoneal cavity that produce the same physiologic alterations as acute appendicitis.

The accuracy of preoperative diagnosis should be higher than 85%. If it is consistently less, it is likely that unnecessary operations are being performed and a more rigorous preoperative differential diagnosis is needed.

The most common findings in the case of an erroneous preoperative diagnosis of appendicitis—together accounting for more than 75% of cases—are, in descending order of frequency, acute mesenteric adenitis, no pathologic condition, acute pelvic inflammatory disease, twisted ovarian cyst or ruptured graafian follicle, and acute gastroenteritis.

The differential diagnosis of acute appendicitis depends on four major factors: the anatomic location of the inflamed appendix; the stage of the process (uncomplicated or complicated); the patient’s age; and the patient’s gender.\textsuperscript{52-56}

**Pediatric Patient.** Acute mesenteric adenitis is the disease most often confused with acute appendicitis in children. Almost invariably, an upper respiratory tract infection is present or has recently subsided. The pain usually is diffuse, and tenderness is not as sharply localized as in appendicitis. Voluntary guarding is sometimes present, but true rigidity is rare. Generalized lymphadenopathy may be noted. Laboratory procedures are of little help in arriving at the correct diagnosis, although a relative lymphocytosis, when present, suggests mesenteric adenitis. Observation for several hours is appropriate if the diagnosis of mesenteric adenitis is suspected, as it is a self-limited disease.

**Elderly Patient.** Diverticulitis or perforating carcinoma of the cecum or of a portion of the sigmoid that overlies the right lower abdomen may be impossible to distinguish from appendicitis. These entities should be considered, particularly in older patients. CT scanning is often helpful in making a diagnosis in older patients with right lower quadrant pain and atypical clinical presentations. In patients successfully managed conservatively, interval surveillance of the colon (colonoscopy or barium enema) may be warranted.

**Female Patient.** Diseases of the female internal reproductive organs that may erroneously be diagnosed as appendicitis are, in approximate descending order of frequency, pelvic inflammatory disease, ruptured graafian follicle, twisted ovarian cyst or tumor, endometriosis, and ruptured ectopic pregnancy. As a result, the rate of misdiagnosis remains higher among female patients.

In pelvic inflammatory disease, the infection is usually bilateral but, if confined to the right tube, may mimic acute appendicitis. Nausea and vomiting are present in patients with appendicitis but in only approximately 50% of those with pelvic

inflammatory disease. Pain and tenderness are usually lower, and motion of the cervix is extremely painful. Intracellular diplococci may be demonstrable on smear of the purulent vaginal discharge. The ratio of cases of appendicitis to cases of pelvic inflammatory disease is low in females in the early phase of the menstrual cycle and high during the luteal phase. The careful clinical use of these features has reduced the incidence of negative findings on laparoscopy in young women to 15%.

Ovulation commonly results in the spillage of sufficient amounts of blood and follicular fluid to produce brief, mild lower abdominal pain. If the amount of fluid is unusually copious and is from the right ovary, appendicitis may be simulated. Pain and tenderness may be rather diffuse, and leukocytosis and fever minimal or absent. Because this pain occurs at the midpoint of the menstrual cycle, it is often called mittelschmerz.

Serous cysts of the ovary are common and generally remain asymptomatic. When right-sided cysts rupture or undergo torsion, the manifestations are similar to those of appendicitis. Patients develop right lower quadrant pain, tenderness, rebound, fever, and leukocytosis. Both transvaginal ultrasonography and CT scanning can be diagnostic.

Torsion requires emergent operative treatment. If the torsion is complete or longstanding, the pedicle undergoes thrombosis, and the ovary and tube become gangrenous and require resection. However, simple detorsion, fenestration of the cyst, and fixation of the ovary as a primary intervention, followed by a laparoscopy a few days later, can be recommended because it is often difficult to preoperatively determine the viability of the ovary.

Blastocysts may implant in the fallopian tube (usually the ampullary portion) and in the ovary. Rupture of right tubal or ovarian pregnancies can mimic appendicitis. Patients may give a history of abnormal menses, either missing one or two periods or noting only slight vaginal bleeding. Unfortunately, patients do not always realize they are pregnant. The development of right lower quadrant or pelvic pain may be the first symptom. The diagnosis of ruptured ectopic pregnancy should be relatively easy. The presence of a pelvic mass and elevated levels of human chorionic gonadotropin are characteristic. Although the leukocyte count rises slightly, the hematocrit level falls as a consequence of the intra-abdominal hemorrhage. Vaginal examination reveals cervical motion and adnexal tenderness, and a more definitive diagnosis can be established by culdocentesis. The presence of blood and particularly decidual tissue is pathognomonic. The treatment of ruptured ectopic pregnancy is emergency surgery.

**Immunosuppressed Patient.** The incidence of acute appendicitis in patients infected with human immunodeficiency virus (HIV) is reported to be 0.5%. This is higher than the 0.1% to 0.2% incidence reported for the general population. The presentation of acute appendicitis in HIV-infected patients is similar to that in noninfected patients. The majority of HIV-infected patients with appendicitis have fever, periumbilical pain radiating to the right lower quadrant (91%), right lower quadrant tenderness (91%), and rebound tenderness (74%). HIV-infected patients do not manifest an absolute leukocytosis; however, if a baseline leukocyte count is available, nearly all HIV-infected patients with appendicitis demonstrate a relative leukocytosis.

The risk of appendiceal rupture appears to be increased in HIV-infected patients. In one large series of HIV-infected patients who underwent appendectomy for presumed appendicitis, 43% of patients were found to have perforated appendicitis at laparotomy. The increased risk of appendiceal rupture may be related to the delay in presentation seen in this patient population. A low CD4 count is also associated with an increased incidence of appendiceal rupture.

The differential diagnosis of right lower quadrant pain is expanded in HIV-infected patients compared with the general population. In addition to the conditions discussed elsewhere in this chapter, opportunistic infections should be considered as a possible cause of right lower quadrant pain. Neutropenic enterocolitis (typhlitis) should also be considered in the differential diagnosis of right lower quadrant pain in HIV-infected patients.

**Initial Management**

**Uncomplicated Appendicitis**

**Operative versus Nonoperative Management of Uncomplicated Appendicitis** In patients with uncomplicated appendicitis, surgical treatment has been the standard of treatment since McBurney reported his experiences. The concept of nonoperative treatment for uncomplicated appendicitis developed from two lines of observations. First, for patients in an environment where surgical treatment is not available (e.g., submarines, expeditions in remote areas), treatment with antibiotics alone was noted to be effective. Second, many patients with signs and symptoms consistent with appendicitis who did not pursue medical treatment would occasionally have spontaneous resolution of their illness.

A handful of observational studies and controlled trials have reported the outcomes of nonoperative versus operative treatment of presumed uncomplicated appendicitis (Table 30-4). Overall, there is a reported 9% short-term (<30 days) failure rate with nonoperative management of appendicitis (13% if evaluated per protocol). In patients in whom nonoperative treatment fails, nearly half of patients have complicated (perforated or gangrenous) appendicitis. After 1 month, about 1% of patients in the trials underwent an interval appendectomy, and 13% of patients who initially were successfully treated with nonoperative measures developed recurrent appendicitis, with an 18% rate of complicated appendicitis. Follow-up was not longer than 1 year in any study. In addition, one-third of patients declined or dropped out from nonoperative management of appendicitis.

In comparison, operative appendectomy demonstrated a relatively low dropout rate (2%), lower proportion of complicated appendicitis (25%), small proportion of a normal appendix (5%), and low rates of superficial surgical site infection (3.7%) and intra-abdominal abscess (1.3%).

The results in these studies must viewed with caution due to unclear selection of patients, incomplete diagnostic workup in the nonoperated patients, unclear gold standard for the operated patients, and high rates of crossover between the treatment arms. The consequences in terms of use of hospital beds, length of hospital stay, morbidity of delayed surgical treatment after failed nonsurgical treatment, delayed diagnosis for patients with an underlying cancer in the appendix or cecum, and risk of increased antibiotic resistance need to be further investigated. Thus, operative treatment of presumed uncomplicated appendicitis still remains the standard of care. Certain subgroups with uncomplicated appendicitis may do well with nonoperative therapy. Patients pursuing nonoperative management should be carefully counseled regarding the risks of treatment failure and recurrent appendicitis.

*Standard deviation.
*Standard error of the mean.
*Study only reported pathology results based on the per-protocol group and not the intent-to-treat group.
*Study did not report the meaning of these values.
*Study did not report the intent-to-treat values; instead, at one institution, 79 of 104 patients declined to be included in the trial.
*These patients declined to be included in the study and opted for surgical management.
NA = not applicable; NR = not reported; PCT = prospective controlled trial; PRCT = prospective randomized controlled trial; RT = retrospective trial; SSI = surgical site infection.
Three retrospective studies have evaluated the role of emergent or urgent surgery for uncomplicated appendicitis: the emergent group had a time from presentation to the operating room of <12 hours, whereas the urgent group had a time from presentation to the operating room of 12 to 24 hours (Table 30-5).61-63 There was no statistically significant increase in the number of complicated appendicitis cases in the urgent group when compared to the emergent group. Similarly, rates of surgical site infection, intra-abdominal abscesses, conversion to an open procedure, or operative time showed no difference between the two groups. While length of stay was longer for the urgent group, it was not statistically or clinically different from the emergent group. Important caveats in consideration of urgent as opposed to emergent surgical care include the patient’s clinical examination, time of presentation from onset of symptoms, and duration of “delay” in surgery. Patients with clinical signs of perforation, patients with delayed presentation of greater than 48 hours from onset of symptoms, and patients whose definitive therapy may be delayed for more than 12 hours were beyond the scope of these studies.

Emergent versus urgent operation for uncomplicated appendicitis is dependent on each institution and surgeon. Institutions without readily available operating rooms and staff may consider performing appendectomy in an urgent fashion as opposed to emergently.

**Complicated Appendicitis.** Complicated appendicitis typically refers to perforated appendicitis commonly associated with an abscess or phlegmon. The yearly incidence rate of perforated appendicitis is about 2 per 10,000 persons and has remarkable little variance over time, geographic region, and age.31,58,69 The proportion of perforated appendicitis, commonly around 25%, is often used as an indicator of quality of care. Differences in this proportion are almost entirely related to differences in the incidence of nonperforated appendicitis. A low proportion of perforations may therefore be the consequence of a higher rate of detection and treatment of early or resolving appendicitis.

Children less than 5 years of age and patients more than 65 years of age have the highest rates of perforation (45% and 51%, respectively). The proportion of perforation increases with increasing duration of symptoms. There is, however, no association of in-hospital delay with perforation. This suggests that most perforations occur early, before the patient arrives to hospital. It has also been proposed that the increasing proportion of perforations with time is explained by selection due to spontaneous resolution of noncomplicated appendicitis.

Perforated appendicitis has been suggested to increase the risk of female infertility due to impaired tubal function, but this has not been shown in epidemiologic studies.70 Rupture should be suspected in the presence of generalized peritonitis and a strong inflammatory response. In many cases, rupture is contained and patients display localized peritonitis. In 2% to 6% of cases, a palpable mass is detected on physical examination. This could represent a phlegmon, which consists of greater than 90% of cases.

NR = not reported; OR = operating room; SSI = surgical site infection.
of matted loops of bowel adherent to the adjacent inflamed appendix or a periappendiceal abscess. Patients who present with a mass have experienced symptoms for a longer duration, usually 5 to 7 days. Distinguishing acute, uncomplicated appendicitis from acute appendicitis with perforation based on clinical findings is often difficult, but it is important to make the distinction because the treatments may differ. CT scan may be beneficial in establishing a diagnosis and guiding therapy.

**Operative versus Nonoperative Management of Complicated Appendicitis**

Patients who present with signs of sepsis and generalized peritonitis should be taken to the operating room immediately with concurrent resuscitation. The surgical approach is based on the surgeon’s level of comfort; however, open appendectomy through a lower midline incision may be necessary to treat these complicated cases.

In patients with complicated appendicitis and a contained abscess or phlegmon but limited peritonitis (focal right lower quadrant pain), the treatment options become more complicated. Often, these patients will require a challenging procedure with a high risk for development of a postoperative intra-abdominal abscess. Options include operative management versus conservative management (antibiotics, bowel rest, fluids, and possible percutaneous drainage).

There have been no prospective randomized controlled studies comparing operative versus conservative management of complicated appendicitis in adults; all studies have been retrospective cohort studies. Two meta-analyses have been performed. In Andersson and Petzold’s 2007 analysis of 61 studies evaluating this issue, they noted that initial nonoperative management had superior outcomes. Nonoperative management included intravenous fluids, minimizing gastrointestinal stimulation, parenteral antibiotics, and percutaneous drainage where deemed appropriate. The morbidity of immediate operative treatment was 36.5%, whereas the morbidity of conservative management was 11%. Of patients undergoing conservative treatment, 7.6% failed conservative treatment and underwent operative management. This subgroup had an overall complication rate of 13.5%. The recurrence rate was 7.4%, which does not necessitate interval appendectomy. The authors concluded that conservative treatment was favored over early operation in complicated appendicitis.

Simillis and colleagues performed a meta-analysis of 17 studies. They noted that conservative treatment was associated with fewer overall complications (odds ratio, 0.24; 95% confidence interval [CI], 0.13 to 0.44), intra-abdominal abscesses (odds ratio, 0.19; 95% CI, 0.07 to 0.58), bowel obstructions (odds ratio, 0.35; 95% CI, 0.17 to 0.71), and reoperations (odds ratio, 0.17; 95% CI, 0.04 to 0.75). The authors concluded that conservative treatment was favored over early operation in complicated appendicitis.

**Interval Appendectomy Following Nonoperative Management of Complicated Appendicitis**

Interval appendectomy is defined as performing an appendectomy following initial successful nonoperative management in patients with no further symptoms. The major argument against interval appendectomy is that many patients treated conservatively never develop manifestations of appendicitis, and those who do generally can be treated without additional morbidity. The major argument for interval appendectomy is to prevent future attacks of appendicitis or to identify other disease, such as appendiceal malignancy.

There has only been one small prospective randomized controlled trial (n = 40) investigating this subject. The literature is largely populated with small case series and retrospective cohort studies; there is no meta-analysis evaluating the subject (Table 30-6). Of the 1434 patients who had presumed complicated appendicitis and were successfully treated conservatively, 8.8% developed recurrent appendicitis with a median follow-up of 35 months. The incidence of complicated appendicitis following recurrence was low (2.4%). Malignancy was noted in 1.3% of cases where pathology was reported. Many of the patients were excluded from these studies due to persistent symptoms, persistent infections, or note of malignancy on screening colonoscopy.

Alternatively, of the 344 patients who had presumed complicated appendicitis, were successfully treated conservatively, and subsequently underwent interval appendectomy, surgical complications occurred in 9.4% of the patients. Most patients underwent interval appendectomy 2 to 4 months after their acute presentation. Although operative and pathologic details were not uniformly reported in these patients, many continued to have evidence of appendicitis or abscess at the time of interval appendectomy; 3.6% of patients had malignancy in cases where pathology was reported.

The role of interval appendectomy following successful management of conservative treatment of complicated appendicitis is unclear. Close clinical follow-up, a complete history searching for persistent symptoms, and screening colonoscopy (when age appropriate) should all be used to help guide the discussion with the patient on the role of interval appendectomy following conservative management of complicated appendicitis.

**Operative Interventions for the Appendix**

**Open Appendectomy**

Typically performed with a patient under general anesthesia, the patient is placed in supine position. The entire abdomen should be prepped and draped in case a larger incision is needed. For early nonperforated appendicitis, a right lower quadrant incision at McBurney’s point (one-third of the distance from the anterior superior iliac spine to the umbilicus) is commonly used. A McBurney (oblique) or Rocky-Davis (transverse) right lower quadrant muscle splitting incision is made. If perforated appendicitis is suspected or the diagnosis is in doubt, a lower midline laparotomy can be considered. Although it has been reported that the position of the base of the appendix can change with pregnancy, prospective studies have demonstrated that pregnancy does not change the proportion of patients with the appendiceal base within 2 cm of McBurney’s point.
Following entry into the abdomen, the patient should be placed in slight Trendelenburg position with rotation of the bed to the patient’s left. If the appendix is not easily identified, the cecum should be located. Tracing the taenia libera (anterior taenia), the most visible of the three taeniae coli, distally, the base of the appendix can be identified.

The appendix will often have attachments to the lateral wall or pelvis that can be dissected free. Dividing the mesentry of the appendix first will often allow improved exposure of the base of the appendix. The appendiceal stump can be managed by simple ligation or by ligation and inversion. As long as the stump is clearly visible and the base of the cecum is not involved with the inflammatory process, the stump can be safely ligated. Obliteration of the mucosa with electrocautery with the intention to obviate the development of a mucocele is recommended by some surgeons; however, no data have evaluated the risk or benefit of this surgical maneuver. Inversion of the stump with plication of the cecum has also been described. Placement of surgical drains for both uncomplicated \(^{83}\) and complicated appendicitis,\(^{84-87}\) practiced by many surgeons, has not been supported in clinical trials. Pus in the abdomen should be aspirated, but irrigation in complicated appendicitis is not recommended.\(^{88}\)

The skin can also be closed primarily in patients with perforated appendicitis.

If appendicitis is not found, a methodical search must be made for an alternative diagnosis. The cecum and mesentery should be inspected. The small bowel should be evaluated in a retrograde fashion beginning at the ileocecal valve. Concerns for Crohn’s disease or Meckel’s diverticulum should be of priority. In female patients, the reproductive organs should be closely inspected. If purulent or bilious fluid is encountered, it is imperative that the source be identified. For example, Valentino’s appendicitis, or a perforated duodenal ulcer presenting as appendicitis, should be excluded in such cases. A medial extension of the incision (Fowler-Weir) or superior extension of the lateral incision is appropriate if further evaluation of the lower abdomen or right colon is warranted. Selective laparoscopy through a right lower quadrant incision has also been described.\(^{89}\) If upper abdominal pathology is encountered, a midline incision should be made.

**Laparoscopic Appendectomy**

The first reported laparoscopic appendectomy was performed in 1983 by Semm; however, the laparoscopic approach did

CS = case series; NR = not reported; PCT = prospective controlled trial; PRCT = prospective randomized controlled trial; RT = retrospective trial.
not come into widespread use until much later, following the success of laparoscopic cholecystectomy. This may be due to the small incision already commonly used with open appendectomy.

Laparoscopic appendectomy is performed under general anesthesia. An oro- or nasogastric tube and urinary catheter are placed. The patient should be placed supine with his or her left arm tucked and securely strapped to the operating table. Both surgeon and assistant should be standing on the patient’s left facing the appendix. The laparoscopic screens should be positioned on the patient’s right or at the foot of the bed. Standard laparoscopic appendectomy typically uses three ports. Typically, a 10- or 12-mm port is placed at the umbilicus, whereas two 5-mm ports are placed suprapubic and in the left lower quadrant. The patient should be placed in Trendelenburg and tilted to the left (Fig. 30-2).

The appendix should be identified similarly as in open surgery by tracking the taenia libera/coli to the appendiceal base. Through the suprapubic port, the appendix should be grasped securely and elevated to the 10 o’clock position. An “appendiceal critical view” should be obtained where the taenia libera is at the 3 o’clock position, the terminal ileum at the 6 o’clock position, and the retracted appendix at the 10 o’clock position to allow proper identification of the base of the appendix (Fig. 30-3). Through the infraumbilical port, the mesentery should be gently dissected from the base of the appendix and a window created. Typically the base of the appendix is stapled, followed by stapling of the mesentery. Alternatively, the mesentery may be divided by an energy device or clipped and the base of the appendix secured with an Endoloop. The stump should be carefully examined to ensure hemostasis, complete transection, and ensure that no stump is left behind. The appendix is removed through the infraumbilical trocar in a retrieval bag.

**Laparoscopic versus Open Appendectomy**

There have been multiple prospective, randomized controlled trials comparing laparoscopic and open appendectomy outcomes. A number of meta-analyses have been performed evaluating the cumulative outcomes (Table 30-7).

Laparoscopic appendectomy is associated with fewer incisional surgical site infections compared to open appendectomy. However, laparoscopic appendectomy may be associated with increased risk of intra-abdominal abscess compared to open appendectomy. There is less pain, shorter length of stay, and...
The vast majority of these cases are hybrid appendectomy when compared to open appendectomy. Laparoscopic appendectomy is associated with increased operative duration and increased operating rooms costs; however, overall costs are likely similar when compared to open appendectomy. Patients tend to have improved satisfaction scores with laparoscopic appendectomy. Many of the differences, while statistically significant, have nominal clinical difference, such as length of stay where differences are measured in hours. In addition, laparoscopic appendectomy may provide a benefit when the diagnosis is in question, such as in female patients of reproductive age, older patients in whom malignancy is suspected, and morbidly obese patients for whom larger open appendectomy incisions may be required.

**Laparoscopic Single-Incision Appendectomy**

There has been growing interest in laparoscopic single-incision appendectomy. Instead of two or three incisions, a single incision is made, typically periumbilical. The first published laparoscopic-assisted, single-incision appendectomy was reported by Inoue in 1994, where the appendix was identified laparoscopically and grasped and pulled through the laparoscopic incision and the appendectomy completed in an open manner. The first reports of a pure laparoscopic single-incision appendectomy were described in 2009 by multiple surgical groups. By this time, industry had designed multiple options for true single-port access as opposed to makeshift single-incision access.

With laparoscopic single-incision appendectomy, the patient is prepared similarly to laparoscopic appendectomy. Under general anesthesia, the patient is secured in a supine position with the left arm tucked. The surgeon and assistant stand on the left side facing the appendix and the screen. When performing laparoscopic single-incision appendectomy, the surgeon’s hands perform the opposite function that they would normally in standard laparoscopic surgery. The surgeon’s right hand will grasp the appendix and retract it to the right lower quadrant at the 10 o’clock position. The surgeon’s left hand will dissect the mesenteric window and, upon identifying the appendiceal critical view, staple across the base of the appendix and mesentery. If the base of the appendix cannot be definitively identified or the appendiceal critical view cannot be obtained, additional ports can be placed to perform a “plus one” or even standard laparoscopic appendectomy. The appendix may be placed in a retrieval bag or removed through the single incision.

There have been multiple small trials evaluating the efficacy of laparoscopic single-incision appendectomy compared to standard appendectomy; however, there has only been one prospective randomized study (in the pediatric population) and one meta-analysis. Gill and colleagues, in 2012, reviewed nine studies for a total of 275 laparoscopic single-incision appendectomies and 348 standard laparoscopic appendectomy procedures. In this meta-analysis, there was no difference in operative time (57 ± 10 vs. 55 ± 13 minutes), complications (11% vs. 8.3%), incisional surgical site infections (5.6% vs. 4.9%), intra-abdominal abscesses (1.8% vs. 1.4%), or length of stay (3 ± 2 vs. 4 ± 1 days). Cases were converted to open or additional ports were placed in 4% of laparoscopic single-incision appendectomies and 0.9% of standard laparoscopic procedures. There was no difference in return to bowel function, postoperative pain, or return to normal activity. There was no difference in overall cost. The incidence of hernia formation following the laparoscopic single-incision appendectomy procedure compared to standard laparoscopy has not been reported.

Although further study is needed, it appears that in laparoscopic appendectomy, laparoscopic single-incision appendectomy conveys no discernible advantage or disadvantage with short-term outcomes. Late outcomes and patient quality-of-life outcomes remain to be investigated.

**Natural Orifice Transluminal Endoscopic Surgery**

Natural orifice transluminal endoscopic surgery (NOTES) is a new surgical procedure using flexible endoscopes in the abdominal cavity. In this procedure, access is gained by way of organs that are reached through a natural, already-existing external orifice. The hoped-for advantages associated with this method include the reduction of postoperative wound pain, shorter convalescence, avoidance of wound infection and abdominal wall hernias, and the absence of scars.

One hundred thirteen NOTES appendectomies in human patients have been reported in the medical literature. Eighty-seven were performed transvaginally, and 26 were performed transgastrically. The vast majority of these cases are hybrid procedures (NOTES plus laparoscopic assist port) with only 14 cases of pure NOTES appendectomies (three transvaginal...

*Index is open.

IAA = intra-abdominal abscess (specifically organ/space surgical site infection); LA = laparoscopic appendectomy; LOS = length of stay; NR = not reported; OA = open appendectomy; SS = statistically significant; SSI = surgical site infection (specifically superficial and deep).
and 11 transgastric). Although reported complication rates appear low, conversion rates (to hybrid procedures) remain high.

The main concern with NOTES has been complications with closure of the enterotomy. To date, there is no reliable method of closure of the gastrotomy site, and there has been significant morbidity reported with this approach.

Although the transvaginal approach appears to be more promising, in women surveyed on their perception of NOTES, three-quarters were either neutral or unhappy about the prospects of NOTES.\textsuperscript{110\textsuperscript{111}}

Much work remains to demonstrate whether NOTES is able to provide the theoretical benefits purported. Great care must be taken to prevent significant morbidity or mortality en route to studying these procedures.

**SPECIAL CIRCUMSTANCES**

**Acute Appendicitis in the Young**

The establishment of a diagnosis of acute appendicitis is more difficult in young children than in the adult. The inability of young children to give an accurate history, diagnostic delays by both parents and physicians, and the frequency of gastrointestinal distress in children are all contributing factors to the misdiagnosis and delay in diagnosis.\textsuperscript{103} In children, the physical examination findings of maximal tenderness in the right lower quadrant, the inability to walk or walking with a limp, and pain with percussion, coughing, and hopping were found to have the highest sensitivity for appendicitis.\textsuperscript{104}

The more rapid progression to rupture and the inability of the underdeveloped greater omentum to contain a rupture lead to significant morbidity rates in children. Children <5 years of age have a negative appendectomy rate of 25% and an appendiceal perforation rate of 45%. These rates may be compared with a negative appendectomy rate of <10% and a perforated appendix rate of 20% in children 5 to 12 years of age.\textsuperscript{50,51} The incidence of major complications after appendectomy in children is correlated with appendiceal rupture. The wound infection rate after the treatment of nonperforated appendicitis in children is 2.8%, compared with a rate of 11% after the treatment of perforated appendicitis. The incidence of intra-abdominal abscess also is higher after the treatment of perforated appendicitis than after nonperforated appendicitis (6% vs. 3%).\textsuperscript{105} The treatment regimen for perforated appendicitis generally includes immediate appendectomy. Antibiotic coverage is limited to 24 to 48 hours in cases of nonperforated appendicitis. For perforated appendicitis, intravenous antibiotics usually are given until the white blood cell count is normal and the patient is afebrile for 24 hours. Laparoscopic appendectomy has been shown to be safe and effective for the treatment of appendicitis in children.\textsuperscript{106}

**Acute Appendicitis in the Elderly**

Compared with younger adults, elderly patients with appendicitis often pose a more difficult diagnostic problem because of the atypical presentation, expanded differential diagnosis, and communication difficulty. These factors may be responsible for the disproportionately high perforation rate seen in the elderly. In the general population, perforation rates range from 20% to 30%, compared with 50% to 70% in the elderly.\textsuperscript{105} In addition, the perforation rate appears to increase with age greater than 80 years.\textsuperscript{108}

Elderly patients usually present with lower abdominal pain, but on clinical examination, localized right lower quadrant tenderness is not as common as in younger patients. A history of periumbilical pain migrating to the right lower quadrant is reported infrequently. Although currently there are no criteria that definitively identify elderly patients with acute appendicitis who are at risk of rupture, prioritization should be given to patients with a temperature of greater than 38°C (100.4°F) and a shift to the left in leukocyte count of more than 76%, especially if they are male, are anorexic, or have had pain of long duration before admission.\textsuperscript{65}

As a result of increased comorbidities and an increased rate of perforation, postoperative morbidity, mortality, and hospital length of stay are increased in the elderly compared with younger populations with appendicitis. Although no randomized trials have been conducted, it appears that elderly patients benefit from a laparoscopic approach to treatment of appendicitis. The use of laparoscopy in the elderly has significantly increased in recent years. In general, laparoscopic appendectomy offers elderly patients with appendicitis a shorter length of hospital stay, a reduction in complication and mortality rates, and a greater chance of discharge to home (independent of further nursing care or rehabilitation).\textsuperscript{109}

**Acute Appendicitis during Pregnancy**

Appendectomy for presumed appendicitis is the most common surgical emergency during pregnancy. The incidence is approximately 1 in 766 births. Acute appendicitis can occur at any time during pregnancy but is rare in the third trimester.\textsuperscript{110} The overall negative appendectomy rate during pregnancy is approximately 25% and appears to be higher than the rate seen in nonpregnant women.\textsuperscript{109,111} A higher rate of negative appendectomy is seen in the second trimester, whereas the lowest rate is in the third trimester. The diversity of clinical presentations and the difficulty in making the diagnosis of acute appendicitis in pregnant women are well established. This is particularly true in the late second trimester and the third trimester, when many abdominal symptoms may be considered pregnancy related. In addition, during pregnancy, there are anatomic changes in the appendix and increased abdominal laxity that may further complicate clinical evaluation.

Appendicitis in pregnancy should be suspected when a pregnant woman complains of abdominal pain of new onset. The most consistent sign encountered in acute appendicitis during pregnancy is pain in the right side of the abdomen. Seventy-four percent of patients report pain located in the right lower abdominal quadrant, with no difference between early and late pregnancy. Only 57% of patients present with the classic history of diffuse periumbilical pain migrating to the right lower quadrant. Laboratory evaluation is not helpful in establishing the diagnosis of acute appendicitis during pregnancy. The physiologic leukocytosis of pregnancy has been defined as high as 16,000 cells/mm$^3$. In one series, only 38% of patients with appendicitis had a white blood cell count of more than 16,000 cells/mm$^3$.\textsuperscript{110} Recent data suggest that the incidence of perforated or complex appendicitis is not increased in pregnant patients.\textsuperscript{111}

When the diagnosis is in doubt, abdominal ultrasound may be beneficial. Another option is magnetic resonance imaging, which has no known deleterious effects on the fetus. The American College of Radiology recommends the use of nonionizing radiation techniques for front-line imaging in...
Laparoscopy has been advocated in equivocal cases, especially early in pregnancy; however, laparoscopic appendectomy may be associated with an increase in pregnancy-related complications. In an analysis of outcomes in California using administrative databases, laparoscopy was found to be associated with a 2.31 times increased risk of fetal loss compared with open surgery. The overall incidence of fetal loss after appendectomy is 4%, and the risk of early delivery is 7%. Rates of fetal loss are considerably higher in women with complicated appendicitis than in those with a negative appendectomy or with simple appendicitis. It is important to note that a negative appendectomy is not a benign procedure. Removing a normal appendix is associated with a 4% risk of fetal loss and 10% risk of early delivery. Maternal mortality after appendectomy is extremely rare (0.03%). Because the incidence of complicated appendix is similar in pregnant and nonpregnant women and because maternal mortality is so low, it appears that the greatest opportunity to improve fetal outcomes is by improving diagnostic accuracy and reducing the rate of negative appendectomy.

### POSTOPERATIVE CARE AND COMPLICATIONS

Following uncomplicated appendectomy, complication rates are low, and most patients can quickly be started on a diet and discharged home the same day or the following day. Postoperative antibiotic therapy is unnecessary. Alternatively, with complicated appendectomy, complication rates are increased compared to uncomplicated appendicitis. Patients should be continued on broad-spectrum antibiotics for 4 to 7 days.

**Surgical Site Infection**

In patients with incisional (superficial or deep) surgical site infection, treatment should be opening of the incision and obtaining a culture. Following laparoscopic appendectomy, the extraction port site is the most common site of surgical site infection. Patients with cellulitis can be started on antibiotics. The cultured organisms are typically bowel flora, as opposed to skin flora.

Patients with postoperative intra-abdominal abscesses can present in a variety of ways. Although fever, leukocytosis, and abdominal pain are common presentations, patients with ileus, bowel obstruction, diarrhea, and tenesmus may also harbor intra-abdominal abscesses. Small abscesses can be simply treated with antibiotics; however, larger abscesses require drainage. Most commonly, percutaneous drainage with CT or ultrasound guidance is effective. For abscesses not amenable to percutaneous drainage, laparoscopic abscess drainage is a viable option.

**Stump Appendicitis**

Incomplete appendectomy represents a failure of removing the entire appendix on the initial procedure. A review of literature has revealed only 60 reports of this phenomenon. Likely, incomplete appendectomy is underreported, and the true prevalence is much higher. Reported as “stump appendicitis,” patients typically present with recurrent symptoms of appendicitis approximately 9 years after their initial surgery. There was no difference in initial surgery between laparoscopic and open procedures. However, there were more complicated appendectomies on initial surgery. Patients presenting with stump appendicitis are more likely to have complicated appendicitis, have an open procedure, and undergo colectomy.

The key to avoiding stump appendicitis is prevention. Use of the “appendiceal critical view” (appendix placed at 10 o’clock, taenia coli/libera at 3 o’clock, and terminal ileum at 6 o’clock) and identification of where the taeniae coli merge and disappear is paramount to identifying and ligating the base of the appendix during the initial operation. The remaining stump should be no longer than 0.5 cm, as stump appendicitis has only been noted in stumps ≥0.5 cm in the literature.

In patients who have had prior appendectomy, a low index of suspicion is important to prevent delay in diagnosis and complications. Prior appendectomy should not be an absolute criterion in ruling out acute appendicitis.

### INCIDENTAL APPENDECTOMY

Decisions regarding the efficacy of incidental appendectomy should be based on the epidemiology of appendicitis. The best data were published by the Centers for Disease Control and Prevention based on the period from 1979 to 1984. During this period, an average of 250,000 cases of appendicitis and 310,000 incidental appendectomies occurred annually in the United States. It was estimated that 36 incidental appendectomies had to be performed to prevent one patient from developing appendicitis. In view of the added costs and risk of morbidity for each extension of a surgical intervention, this does not seem to justify incidental appendectomy.

The financial aspects of the decision to perform incidental appendectomy were assessed. For open appendectomy, there was a financial disincentive to perform incidental appendectomy. On an annual basis, $20,000,000 had to be spent to save the $6,000,000 cost of appendicitis. With the laparoscopic approach, it was cost-effective to perform incidental appendectomy only in patients less than 25 years of age and only if the reimbursement for surgeons was 10% of the usual and customary charges. At a higher rate of reimbursement, incidental appendectomy was not cost-effective in any age group.

Although incidental appendectomy is generally neither clinically nor economically appropriate, there are some special patient groups in whom it should be performed during laparotomy or laparoscopy for other indications. These include children about to undergo chemotherapy, the disabled who cannot describe symptoms or react normally to abdominal pain, patients with Crohn’s disease in whom the cecum is free of macroscopic disease, and individuals who are about to travel to remote places where there is no access to medical or surgical care.

Appendectomy is routinely carried out during the performance of Ladd’s procedure for malrotation because displacement of the cecum into the left upper quadrant would complicate the diagnosis of subsequent appendicitis.

### NEOPLASMS OF THE APPENDIX

#### Prevalence of Neoplasms

Multiple studies have evaluated the prevalence of mass lesions present in appendectomy specimens (Table 30-8). The prevalence of identifying a mass within the appendix is less than 1%. Appendiceal carcinoid and appendiceal adenomas are the most common lesions identified. There is no clear age relationship associated with the identification of these masses.
In older patients, the prevalence of identifying colon cancer appearing as appendicitis has been reported in a single study with a prevalence of less than 1%. The mean age in this case series was 69 years (range, 42 to 89 years).

**Carcinoid**

The finding of a firm, yellow, bulbar mass in the appendix should raise the suspicion of an appendiceal carcinoid. The appendix is the most common site of gastrointestinal carcinoid, followed by the small bowel and rectum. Carcinoid syndrome is rarely associated with appendiceal carcinoid unless widespread metastases are present, which occur in 2.9% of cases. Symptoms attributable directly to the carcinoid are rare, although the tumor can occasionally obstruct the appendiceal lumen much like a fecalith and result in acute appendicitis.

The majority of carcinoids are located in the tip of the appendix. Malignant potential is related to size, with tumors <1 cm rarely resulting in extension outside of the appendix or adjacent to the mass. The mean tumor size for carcinoids is 2.5 cm. Carcinoid tumors usually present with localized disease (64%). Treatment for tumors ≤1 cm is appendectomy. For tumors larger than 1 to 2 cm located at the base, involving the mesentery, or with lymph node metastases, right hemicolectomy is indicated. Despite these recommendations, surveillance, epidemiology, and end results data indicate that proper surgery for carcinoids is not performed at least 28% of the time.

**Adenocarcinoma**

Primary adenocarcinoma of the appendix is a rare neoplasm with three major histologic subtypes: mucinous adenocarcinoma, colonic adenocarcinoma, and adenocarcinoid. The most common mode of presentation for appendiceal carcinoma is that of acute appendicitis. Patients may also present with ascites or a palpable mass, or the neoplasm may be discovered during an operative procedure for an unrelated cause. The recommended treatment for all patients with adenocarcinoma of the appendix is a formal right hemicolectomy. Appendiceal adenocarcinomas are associated with mucinous appendiceal adenocarcinoma and are at significant risk for both synchronous and metachronous neoplasms, approximately half of which will originate from the gastrointestinal tract.

**Mucocele**

A mucocele of the appendix is an obstructive dilatation by intraluminal accumulation of mucoid material. Mucoceles may be caused by one of four processes: retention cysts, mucosal hyperplasia, cystadenomas, and cystadenocarcinomas. The clinical presentation of a mucocele is nonspecific, and often it is an incidental finding at operation for acute appendicitis. An intact mucocele presents no future risk for the patient; however, the opposite is true if the mucocele has ruptured and epithelial cells have escaped into the peritoneal cavity. As a result, when a mucocele is visualized at the time of laparoscopic examination, conversion to open laparotomy is recommended. Conversion from a laparoscopic approach to a laparotomy ensures that a benign process will not be converted to a malignant one through mucocele rupture. In addition, laparotomy allows for thorough abdominal exploration to rule out the presence of mucoid fluid accumulations.

The presence of a mucocele of the appendix does not mandate performance of a right hemicolectomy. The principles of surgery include resection of the appendix, wide resection of the mesoappendix to include all the appendiceal lymph nodes, collection and cytologic examination of all intraperitoneal mucus, and careful inspection of the base of the appendix. Right hemicolecotomy or, preferably, ileocecectomy is reserved for patients with a positive margin at the base of the appendix or positive perappendiceal lymph nodes. Recently, a more aggressive approach to ruptured appendiceal neoplasms has been advocated. This approach includes a thorough but minimally aggressive approach at initial laparotomy, as described earlier, with subsequent referral to a specialized center for consideration of reexploration and hyperthermic intraperitoneal chemotherapy.

**Pseudomyxoma Peritonei**

Pseudomyxoma peritonei is a rare condition in which diffuse collections of gelatinous fluid are associated with mucinous
implants on peritoneal surfaces and omentum. Pseudomyxoma is two to three times more common in females than in males. Recent immunocytologic and molecular studies suggest that the appendix is the site of origin for the overwhelming majority of cases of pseudomyxoma. Pseudomyxoma is invariably caused by neoplastic mucus-secreting cells within the peritoneum. These cells may be difficult to classify as malignant because they may be sparse, widely scattered, and have a low-grade cytologic appearance. Patients with pseudomyxoma usually present with abdominal pain, distention, or a mass. Primary pseudomyxoma usually does not cause abdominal organ dysfunction. However, ureteral obstruction and obstruction of venous return can be seen. Pseudomyxoma is a disease that progresses slowly and in which recurrences may take years to develop or become symptomatic. In a series from the Mayo Clinic, 76% of patients developed recurrences within the abdomen. Lymph node metastasis and distant metastases are uncommon.

The use of imaging before surgery is advantageous to plan surgery. CT scanning is the preferred imaging modality. At surgery, a variable volume of mucinous ascites is found together with tumor deposits involving the right hemidiaphragm, right retroperitoneal space, left paracolic gutter, ligament of Treitz, and the ovaries in women. Peritoneal surfaces of the bowel are usually free of tumor. Though surgical debulking is the mainstay of treatment. All gross disease and the omentum should be removed. If not done previously, appendectomy is routinely performed. Hysterectomy with bilateral salpingo-oophorectomy is performed in women. Survival is better in patients who undergo R0 or R1 resection than in patients who undergo R2 resection (visible gross disease remaining). Because 5-year survival of mucinous appendiceal neoplasms is only 30%, adjuvant intraperitoneal hyperthermic chemotherapy is advocated as a standard adjunct to radical cytoreductive surgery. Cytoreductive surgery with intraperitoneal hyperthermic chemotherapy is a long, tedious procedure with operative times of 300 to 1020 minutes reported. In addition, morbidity (38%) and mortality (6%) are high. Cytoreductive surgery with intraperitoneal hyperthermic chemotherapy is associated with a 5-year survival rate of 53% to 78%. Survival is associated with initial patient performance status.

Any recurrence should be investigated completely. Recurrences are usually treated by additional surgery. It is important to note that surgery for recurrent disease is usually difficult and is associated with an increased incidence of enterotomies, anastomotic leaks, and fistulas.

**Lymphoma**

Lymphoma of the appendix is extremely uncommon. The gastrointestinal tract is the most frequently involved extranodal site for non-Hodgkin’s lymphoma. Other types of appendiceal lymphoma, such as Burkitt’s lymphoma, as well as leukemia, have also been reported. Primary lymphoma of the appendix accounts for 1% to 3% of gastrointestinal lymphomas. Appendiceal lymphoma usually presents as acute appendicitis and is rarely suspected preoperatively. Findings on CT scan of an appendiceal diameter ≥2.5 cm or surrounding soft tissue thickening should prompt suspicion of an appendiceal lymphoma. The management of appendiceal lymphoma confined to the appendix is appendectomy. Right hemicolectomy is indicated if tumor extends beyond the appendix onto the cecum or mesentery. A postoperative staging workup is indicated before initiating adjuvant therapy. Adjuvant therapy is not indicated for lymphoma confined to the appendix.

The ancient Greek myth of Prometheus reminds us that the liver is the only organ that regenerates. According to Greek mythology, Zeus was furious with the Titan Prometheus because he gave fire to mortals. In return, Zeus chained Prometheus to Mount Caucasus and sent his giant eagle to eat his liver during the day, only to have it regenerate at night. Although this is folklore, the principles are correct that after hepatic resection, the remnant liver will hypertrophy over weeks to months to regain most of its original liver mass. It is interesting to note that the ancient Greeks seem to have been aware of this fact, because the Greek word for the liver, hépar, derives from the verb hépaomai, which means “mend” or “repair.” Hence hépar roughly translates as “repairable.” The importance of the liver dates back to even biblical times, for the Babylonians (c. 2000 B.C.) considered the liver to be the seat of the soul. There are scattered reports of liver surgery for battlefield injuries, but the first recorded elective hepatic resection was done in 1888 in Germany by Langenbuch. There followed reports of liver resections in the United States (Tiffany, 1890) and Europe (Lucke, 1891), as well as the first large series of hepatic resections by Keen in 1899. In 1908, Pringle described in Annals of Surgery the “arrest of hepatic hemorrhage due to trauma” by compression of the porta hepatis, a maneuver that now bears his name. Possibly due to the potential for massive hemorrhage during liver surgery, very little progress in surgical techniques was recorded for the next half-century. Work by Rex, Cantlie, and others laid the groundwork for experimental and clinical reports in the 1950s by Couinaud, Hjortsjo, Healey, Lortat-Jacob, and Starzl. These seminal contributions paved the way for the modern era of hepatic resection surgery.

**HISTORY OF LIVER SURGERY**

The liver is the largest organ in the body, weighing approximately 1500 g. It resides in the right upper abdominal cavity beneath the diaphragm and is protected by the rib cage. It is reddish brown and is surrounded by a fibrous sheath known as Glisson’s capsule. The liver is held in place by several ligaments (Fig. 31-1). The round ligament is the remnant of the obliterated umbilical vein and enters the left liver hilum at the front edge of the falciform ligament. The falciform ligament separates the left lateral and left medial segments along the umbilical fissure and anchors the liver to the anterior abdominal wall. Deep in the plane between the caudate lobe and the left lateral segment is the fibrous ligamentum venosum (Arantius’ ligament), which is the obliterated ductus venosus and is covered by the plate of Arantius. The left and right triangular ligaments secure the two sides of the liver to the diaphragm. Extending from the triangular ligaments anteriorly on the liver are the coronary ligaments. The right coronary ligament also extends from the right undersurface of the liver to the peritoneum overlying the right kidney, thereby anchoring the liver to the right retroperitoneum. These ligaments (round, falciform, triangular, and coronary) can be divided in a bloodless plane to fully mobilize the liver to facilitate hepatic resection. Centrally and just to the left of the gallbladder fossa, the liver attaches via the hepatoduodenal ligament and the gastrohepatic ligaments (Fig. 31-2). The hepatoduodenal ligament is known as the porta hepatis and contains the common bile duct, the hepatic artery, and the portal vein. From the right side and deep (dorsal) to the porta hepatis is the foramen of Winslow, also known as the epiploic foramen (see Fig. 31-2). This passage connects directly to the lesser sac and allows complete vascular inflow control to the liver when the hepatoduodenal ligament is clamped using the Pringle maneuver.

**LIVER ANATOMY**

The liver is the largest gland in the body and performs a diverse spectrum of functions.

1. The liver is the largest gland in the body and performs a diverse spectrum of functions.
2. Acute liver failure rapidly progresses to hepatic coma and death even with maximal medical therapy. The only definitive treatment is orthotopic liver transplantation.
3. Cirrhosis is the end result of chronic hepatic insult, and further deterioration can lead to the development of end-stage liver disease, which carries a high mortality rate.
4. Acute variceal bleeding should be managed with aggressive resuscitation and prompt endoscopic diagnosis with hemorrhage control. The transjugular intrahepatic portosystemic shunt procedure can be considered for cases refractory to medical treatment.
5. Common benign lesions of the liver include cysts, hemangiomas, focal nodular hyperplasia, and hepatocellular adenomas. In most instances, these lesions can be reliably diagnosed by their characteristic features on imaging.
6. Many options exist for the treatment of hepatocellular carcinomas, and these cases are best managed by a multidisciplinary liver transplant team.
7. Surgical resection is the treatment of choice for hilar cholangiocarcinoma. Under a protocol with strict eligibility criteria, patients with unresectable tumors can be considered for liver transplantation following neoadjuvant chemoradiation, with survival rates that compare favorably with the rates for resection.
8. The resectability of colorectal cancer metastases to the liver is primarily determined by the volume of the future liver remnant and the health of the background liver and not actual tumor number.
9. Laparoscopic liver resections can be performed safely by experienced surgeons in selected patients and have been shown to produce comparable morbidity and mortality rates to open resections.

**Key Points**

1. When operating on the liver, gallbladder, pancreas, or adjacent organs, recognition of the normal or variant vascular and biliary anatomy is essential to avoiding surgical complications.
2. The liver is the largest gland in the body and performs a diverse spectrum of functions.
3. Computed tomography and magnetic resonance imaging with contrast enhancement constitute the mainstays for the radiologic evaluation of the liver.
4. Acute liver failure rapidly progresses to hepatic coma and death even with maximal medical therapy. The only definitive treatment is orthotopic liver transplantation.
5. Cirrhosis is the end result of chronic hepatic insult, and further deterioration can lead to the development of end-stage liver disease, which carries a high mortality rate.
6. Acute variceal bleeding should be managed with aggressive resuscitation and prompt endoscopic diagnosis with hemorrhage control. The transjugular intrahepatic portosystemic shunt procedure can be considered for cases refractory to medical treatment.
7. Common benign lesions of the liver include cysts, hemangiomas, focal nodular hyperplasia, and hepatocellular adenomas. In most instances, these lesions can be reliably diagnosed by their characteristic features on imaging.
8. Many options exist for the treatment of hepatocellular carcinomas, and these cases are best managed by a multidisciplinary liver transplant team.
9. Surgical resection is the treatment of choice for hilar cholangiocarcinoma. Under a protocol with strict eligibility criteria, patients with unresectable tumors can be considered for liver transplantation following neoadjuvant chemoradiation, with survival rates that compare favorably with the rates for resection.
10. The resectability of colorectal cancer metastases to the liver is primarily determined by the volume of the future liver remnant and the health of the background liver and not actual tumor number.
11. Laparoscopic liver resections can be performed safely by experienced surgeons in selected patients and have been shown to produce comparable morbidity and mortality rates to open resections.
Segmental Anatomy

The liver is grossly separated into the right and left lobes by the plane from the gallbladder fossa to the inferior vena cava (IVC), known as Cantlie’s line. The right lobe typically accounts for 60% to 70% of the liver mass, with the left lobe (and caudate lobe) making up the remainder. The caudate lobe lies to the left and anterior of the IVC and contains three subsegments: the Spiegel lobe, the paracaval portion, and the caudate process. The falciform ligament does not separate the right and left lobes, but rather it divides the left lateral segment from the left medial segment. The left lateral and left medial segments also are referred to as sections as defined in the Brisbane 2000 terminology, which is outlined later in the section titled “Hepatic Resection.”

A significant advance in our understanding of liver anatomy came from the cast work studies of the French surgeon and anatomist Couinaud in the early 1950s. Couinaud divided the liver into eight segments, numbering them in a clockwise direction beginning with the caudate lobe as segment I. Segments II and III comprise the left lateral segment, and segment IV is the left medial segment (Fig. 31-3). Thus, the left lobe is made up of the left lateral segment (Couinaud’s segments II and III) and the left medial segment (segment IV). Segment IV can be subdivided into segment IVA and segment IVB. Segment IVA is cephalad and just below the diaphragm, spanning from segment VIII to the falciform ligament adjacent to segment II. Segment IVB is caudad and adjacent to the gallbladder fossa. Many anatomy textbooks also refer to segment IV as the quadrate lobe. Quadrate lobe is an outdated term, and the preferred term is segment IV or left medial segment. Most surgeons still refer to segment I as the caudate lobe, rather than segment I. The right lobe is comprised of segments V, VI, VII, and...
VIII, with segments V and VIII making up the right anterior lobe, and segments VI and VII the right posterior lobe.

Additional functional anatomy was highlighted by Bismuth based on the distribution of the hepatic veins. The three hepatic veins run in corresponding scissura (fissures) and divide the liver into four sectors. The right hepatic vein runs along the right scissura and separates the right posterolateral sector from the right anterolateral sector. The main scissura contains the middle hepatic vein and separates the right and left livers. The left scissura contains the course of the left hepatic vein and separates the left posterior and left anterior sectors.

**Hepatic Artery**

The liver has a dual blood supply consisting of the hepatic artery and the portal vein. The hepatic artery delivers approximately 25% of the blood supply, and the portal vein approximately 75%. The hepatic artery arises from the celiac axis (trunk), which gives off the left gastric, splenic, and common hepatic arteries (Fig. 31-4). The common hepatic artery then divides into the gastroduodenal artery and the hepatic artery proper. The right gastric artery typically originates off of the hepatic artery proper, but this is variable. The hepatic artery proper divides into the right and left hepatic arteries. This “classic” or standard arterial anatomy is present in only approximately 76% of cases, with the remaining 24% having variable anatomy. It is critical to understand the arterial (and biliary) anatomic variants to avoid surgical complications when operating on the liver, gallbladder, pancreas, or adjacent organs.

The most common hepatic arterial variants are shown (Fig. 31-5). Approximately 10% to 15% of the time, there is a replaced right hepatic artery from SMA (10%-15%). Approximately 3% to 10% of the time, there is a replaced left hepatic artery from left gastric artery. Approximately 1% to 2% of the time, there is a replaced right and replaced left hepatic arteries. Approximately 1% to 2% of the time, there is a completely replaced common hepatic artery from SMA.
replaced or accessory right hepatic artery arising from the superior mesenteric artery (SMA). When there is a replacement or accessory right hepatic artery, it travels posterior to the portal vein and then takes up a right lateral position before diving into the liver parenchyma. This can be recognized visually on a preoperative computed tomography (CT) or magnetic resonance imaging (MRI) scan, and confirmed by palpation in the hilum where a separate right posterior pulsation is felt distinct from that of the hepatic artery proper that lies anteriorly in the hepatoduodenal ligament to the left of the common bile duct. In approximately 3% to 10% of cases, there exists a replacement (or accessory) left hepatic artery coming off of the left gastric artery and running obliquely in the gastrohepatic ligament anterior to the caudate lobe before entering the hilar plate at the base of the umbilical fissure. Other less common variants (approximately 1% to 2% each) are the presence of both replaced right and replaced left hepatic arteries, as well as a completely replaced common hepatic artery coming off the SMA (see Fig. 31-5). Although not well demonstrated in the illustration, the clue for a completely replaced common hepatic artery coming off the SMA is the presence of a strong arterial pulsation to the right of and posterior to the common bile duct, rather than the left side and anterior, in the porta hepatis. Another important point is that the right hepatic artery passes deep and posterior to the common bile duct approximately 88% of the time but crosses anterior to the common bile duct in approximately 12% of cases. The cystic artery feeding the gallbladder usually arises from the right hepatic artery in Calot’s triangle.

**Portal Vein**

The portal vein is formed by the confluence of the splenic vein and the superior mesenteric vein. The inferior mesenteric vein usually drains into the splenic vein upstream from the confluence (Fig. 31-6). The main portal vein traverses the porta hepatitis before dividing into the left and right portal vein branches. The left portal vein typically branches from the main portal vein outside of the liver with a sharp bend to the left and consists of the transverse portion followed by a 90° turn at the base of the umbilical fissure to become the umbilical portion before entering the liver parenchyma (Fig. 31-7). The left portal vein then divides to give off the segment II and III branches to the left lateral segment, as well as the segment IV branches that supply the left medial segment. The left portal vein also provides the dominant inflow branch to the caudate lobe (although branches can arise from the main and right portal veins also), usually close to the bend between the transverse and umbilical portions. The division of the right portal vein is usually higher in the hilum and may be close to (or inside) the liver parenchyma at the hilal plate. Twenty percent to thirty-five percent of individuals have aberrant portal venous anatomy, with portal vein trifurcation or an aberrant branch from the left portal vein supplying the right anterior lobe being the most frequent.

The portal vein drains the splanchnic blood from the stomach, pancreas, spleen, small intestine, and majority of the colon to the liver before returning to the systemic circulation. The portal vein pressure in an individual with normal physiology is low at 3 to 5 mmHg. The portal vein is valveless, however, and in the setting of portal hypertension, the pressure can be quite high (20 to 30 mmHg). This results in decompression of the systemic circulation through portocaval anastomoses, most commonly via the coronary (left gastric) vein, which produces esophageal and gastric varices with a propensity for major hemorrhage. Another branch of the main portal vein is the superior pancreaticoduodenal vein (which comes off low in an anterior lateral position and is divided during pancreaticoduodenectomy). Closer to the liver, the main portal vein typically gives off a short branch (posterior lateral) to the caudate process on the right side. It is important to identify this branch and ligate it during hilar dissection for anatomic right hemihepatectomy to avoid avulsion.

**Hepatic Veins and Inferior Vena Cava**

There are three hepatic veins (right, middle, and left) that pass obliquely through the liver to drain the blood to the suprahepatic IVC and eventually the right atrium (Fig. 31-8). The right hepatic vein drains segments V through VIII; the middle hepatic vein drains segment IV as well as segments V and VIII; and the left hepatic vein drains segments II and III. The caudate lobe is unique because its venous drainage feeds directly into the IVC. In addition, the liver usually has a few small, variable short hepatic veins that directly enter the IVC from the undersurface of the liver. The left and middle hepatic veins form a common trunk approximately 95% of the time before entering the IVC, whereas the right hepatic vein inserts separately (in an oblique orientation) into the IVC.

**Figure 31-6.** Portal vein anatomy. The portal vein is formed by the confluence of the splenic and superior mesenteric veins. The inferior mesenteric vein drains into the splenic vein. The coronary (left gastric) vein drains into the portal vein in the vicinity of the confluence. v. = vein.

**Figure 31-7.** Anatomy of the left portal vein (LPV). Cadaver cast shows the transverse and umbilical portions of the LPV.
There is a large inferior accessory right hepatic vein in 15% to 20% of cases that runs in the hepatocaval ligament. This can be a source of torrential bleeding if control of it is lost during right hepatectomy. The hepatic vein branches bisect the portal branches inside the liver parenchyma (i.e., the right hepatic vein runs between the right anterior and posterior portal veins; the middle hepatic vein passes between the right anterior and left portal vein; and the left hepatic vein crosses between the segment II and III branches of the left portal vein).

Bile Duct and Hepatic Ducts
Within the hepatoduodenal ligament, the common bile duct lies anteriorly and to the right. It gives off the cystic duct to the gallbladder and becomes the common hepatic duct before dividing into the right and left hepatic ducts. In general, the hepatic ducts follow the arterial branching pattern inside the liver. The right anterior hepatic duct usually enters the liver above the hilar plate, whereas the right posterior duct diverges behind the right portal vein and can be found on the surface of the caudate process before entering the liver. The left hepatic duct typically has a longer extrahepatic course before giving off segmental branches behind the left portal vein at the base of the umbilical fissure. Considerable variation exists, and in 30% to 40% of cases, there is a nonstandard hepatic duct confluence with accessory or aberrant ducts (Fig. 31-9). The cystic duct itself also has a variable pattern of drainage into the common bile duct. This can lead to potential injury or postoperative bile leakage during cholecystectomy or hepatic resection, and the surgeon needs to expect these variants. The gallbladder sits adherent to hepatic segments IVB (left lobe) and V (right lobe).

Neural Innervation and Lymphatic Drainage
The parasympathetic innervation of the liver comes from the left vagus, which gives off the anterior hepatic branch, and the right vagus, which gives off the posterior hepatic branch. The sympathetic innervation involves the greater thoracic splanchnic nerves and the celiac ganglia, although the function of these nerves is poorly understood. The denervated liver after hepatic transplantation seems to function with normal capacity. A common source of referred pain to the right shoulder and scapula as well as the right side or back is the right phrenic nerve, which is stimulated by tumors that stretch Glisson’s capsule or by diaphragmatic irritation.

Lymph is produced within the liver and drains via the perisinusoidal space of Disse and periportal clefts of Mall to larger lymphatics that drain to the hilar cystic duct lymph node.
(Calot’s triangle node), as well as the common bile duct, hepatic artery, and retropancreatic and celiac lymph nodes. This is particularly important for resection of hilar cholangiocarcinoma, which has a high incidence of lymph node metastases. The hepatic lymph also drains cephalad to the cardiophrenic lymph nodes, and the latter can be pathologically identified on a staging CT or MRI scan.

**LIVER PHYSIOLOGY**

The liver is the largest gland in the body and has an extraordinary spectrum of functions. These include processes such as storage, metabolism, production, and secretion. One crucial role is the processing of absorbed nutrients through the metabolism of glucose, lipids, and proteins. The liver maintains glucose concentrations in a normal range over both short and long periods by performing several important roles in carbohydrate metabolism. In the fasting state, the liver ensures a sufficient supply of glucose to the central nervous system. The liver can produce glucose by breaking down glycogen through glycogenolysis and by de novo synthesis of glucose through gluconeogenesis from noncarbohydrate precursors such as lactate, amino acids, and glycerol. In the postprandial state, excess circulating glucose is removed by glycogen synthesis or glycolysis and lipogenesis. The liver also plays a central role in lipid metabolism through the formation of bile and the production of cholesterol and fatty acids. Protein metabolism occurs in the liver through amino acid deamination, resulting in the production of ammonia as well as the production of a variety of amino acids. In addition to metabolism, the liver also is responsible for the synthesis of most circulating plasma proteins. Among these proteins are albumin, factors of the coagulation and fibrinolytic systems, and compounds of the complement cascade. Furthermore, the detoxification of many substances through drug metabolism occurs in the
liver, as do immunologic responses through the many immune cells found in its reticuloendothelial system. 

Bilirubin Metabolism

Bilirubin is the breakdown product of normal heme catabolism. Bilirubin is bound to albumin in the circulation and sent to the liver. In the liver, it is conjugated to glucuronic acid to form bilirubin diglucuronide in a reaction catalyzed by the enzyme glucuronyl transferase, making it water soluble. This glucuronide is then excreted into the bile canaliculi. A small amount dissolves in the blood and is then excreted in the urine. The majority of conjugated bilirubin is excreted in the intestine as waste, because the intestinal mucosa is relatively impermeable to conjugated bilirubin. However, it is permeable to unconjugated bilirubin and urobilinogens, a series of bilirubin derivatives formed by the action of bacteria. Thus, some of the bilirubin and urobilinogens are reabsorbed in the portal circulation; they are again excreted by the liver or enter the circulation and are excreted in the urine.

Formation of Bile

Bile is a complex fluid containing organic and inorganic substances dissolved in an alkaline solution that flows from the liver through the biliary system and into the small intestine. The main components of bile are water, electrolytes, and a variety of organic molecules including bile pigments, bile salts, phospholipids (e.g., lecithin), and cholesterol. The two fundamental roles of bile are to aid in the digestion and absorption of lipids and lipid-soluble vitamins and to eliminate waste products (bilirubin and cholesterol) through secretion into bile and elimination in feces. Bile is produced by hepatocytes and secreted through the biliary system. In between meals, bile is stored in the gallbladder and concentrated through the absorption of water and electrolytes. Upon entry of food into the duodenum, bile is released from the gallbladder to aid in digestion. The human liver can produce about 1 L of bile daily.

Bile salts, in conjunction with phospholipids, are responsible for the digestion and absorption of lipids in the small intestine. Bile salts are sodium and potassium salts of bile acids conjugated to amino acids. The bile acids are derivatives of cholesterol synthesized in hepatocytes. Cholesterol, ingested from the diet or derived from hepatic synthesis, is converted into the bile acids cholic acid and chenodeoxycholic acid. These bile acids are conjugated to either glycine or taurine before secretion into the biliary system. Bacteria in the intestine can remove glycine and taurine from bile salts. They can also convert some of the primary bile acids into secondary bile acids by removing a hydroxyl group, producing deoxycholic acid from cholic acid and lithocholic acid from chenodeoxycholic acid.

Bile salts secreted into the intestine are efficiently reabsorbed and reused. Approximately 90% to 95% of the bile salts are absorbed from the small intestine at the terminal ileum. The remaining 5% to 10% enter the colon and are converted to the secondary salts, deoxycholic acid and lithocholic acid. The mixture of primary and secondary bile salts and bile acids is absorbed primarily by active transport in the terminal ileum. The absorbed bile salts are transported back to the liver in the portal vein and re-excreted in the bile. Those lost in the stool are replaced by synthesis in the liver. The continuous process of secretion of bile salts in the bile, their passage through the intestine, and their subsequent return to the liver is termed the enterohepatic circulation.

Drug Metabolism

The liver plays an important role in providing mechanisms for ridding the body of foreign molecules (xenobiotics) that are absorbed from the environment. In most cases, a drug is relatively lipophilic to ensure good absorption. The liver participates in the elimination of these lipid-soluble drugs by transforming them into more readily excreted hydrophilic products. There are two main reactions important for drug metabolism. Phase I reactions include oxidation, reduction, and hydrolysis of molecules. These result in metabolites that are more hydrophilic than the original chemicals. The cytochrome P450 system is a family of hemoproteins important for oxidative reactions involving drugs and toxic substances. Phase II reactions, also known as conjugation reactions, are synthetic reactions that involve addition of subgroups to the drug molecule. These subgroups include glucuronate, acetate, glutathione, glycine, sulfate, and methyl groups. These drug reactions occur mainly in the smooth endoplasmic reticulum of hepatocytes.

Many factors can affect drug metabolism in the liver. When the rate of metabolism of a drug is increased (i.e., enzyme induction), the duration of the drug action will decrease. However, when the metabolism of a drug is decreased (i.e., enzyme inhibition), then the drug will circulate for a longer period of time. It is important to note that some drugs may be converted to active products by metabolism in the liver. An example is acetaminophen when taken in larger doses. Normally, acetaminophen is conjugated by the liver to harmless glucuronide and sulfate metabolites that are water soluble and eliminated in the urine. During an overdose, the normal metabolic pathways are overwhelmed, and some of the drug is converted to a reactive and toxic intermediate by the cytochrome P450 system. Glutathione normally reacts with this intermediate, leading to the production and subsequent excretion of a harmless product. However, as glutathione stores are diminished, the reactive intermediate cannot be detoxified and it combines with lipid membranes of hepatocytes, which results in cellular necrosis. Thus, treatment of acetaminophen overdoses consists of replenishing glutathione stores by supplementing with sulfhydryl compounds such as acetylcysteine.

Liver Function Tests

Liver function tests is a term frequently used to refer to measurement of the levels of a group of serum markers for evaluation of liver dysfunction. Most commonly, levels of aspartate transaminase (AST), alanine transaminase (ALT), alkaline phosphatase (AP), γ-glutamyltranspeptidase (GGT), and bilirubin are included in this panel. This term is a misnomer, however, because most of these tests measure not liver function but rather cell damage. More accurate measurement of the liver’s synthetic function is provided by serum albumin levels and prothrombin time (PT). Although measuring liver enzyme levels is important in the assessment of a patient’s liver disease, these test results can be nonspecific. Thus, evaluation of patients with suspected liver disease should always involve careful interpretation of abnormalities in these liver test results in the context of a thorough history and physical examination. The approach to evaluating abnormal laboratory values also can be simplified by categorizing the type of abnormality that predominates (hepatocellular damage, abnormal synthetic function, or cholestasis).

Hepatocellular Injury

Hepatocellular injury of the liver is usually indicated by abnormalities in levels of the liver aminotransferases AST and ALT.
These enzymes participate in gluconeogenesis by catalyzing the transfer of amino groups from aspartic acid or alanine to ketoglutaric acid to produce oxalacetic acid and pyruvic acid, respectively (these enzymes are also referred to as serum glutamic-oxaloacetic transaminase [SGOT] and serum glutamic-pyruvic transaminase [SGPT]). AST is found in liver, cardiac muscle, skeletal muscle, kidney, brain, pancreas, lungs, and red blood cells and thus is less specific for disorders of the liver. ALT is predominately found in the liver and thus is more specific for liver disease. Hepatocellular injury is the trigger for release of these enzymes into the circulation. Common causes of elevated aminotransferase levels include viral hepatitis, alcohol abuse, medications, genetic disorders (Wilson’s disease, hemochromatosis, α₁-antitrypsin deficiency), and autoimmune diseases.

The extent of serum aminotransferase elevations can suggest certain etiologies of the liver injury. However, the levels of the enzymes in these tests correlate poorly with the severity of hepatocellular necrosis, because they may not be significantly elevated in conditions of hepatic fibrosis or cirrhosis. In alcoholic liver disease, an AST:ALT ratio of >2:1 is common. Mild elevations of transaminase levels can be found in nonalcoholic fatty liver disease, chronic viral infection, or medication-induced injury. Moderate increases in the levels of these enzymes are common in acute viral hepatitis. In conditions of ischemic insults, toxin ingestions (i.e., acetaminophen), and fulminant hepatitis, AST and ALT levels can be elevated to the thousands.

**Abnormal Synthetic Function**

Albumin synthesis is an important function of the liver and thus can be measured to evaluate the liver’s synthetic function. The liver produces approximately 10 g of albumin per day. However, albumin levels are dependent on a number of factors such as nutritional status, renal dysfunction, protein-losing enteropathies, and hormonal disturbances. In addition, level of albumin is not a marker of acute hepatic dysfunction due to albumin’s long half-life of 15 to 20 days.

Most clotting factors (except factor VIII) are synthesized exclusively in the liver, and thus their levels can also be used as a measure of hepatic synthetic function. Measurements of the prothrombin time (PT) and international normalized ratio (INR) are some of the best tests of hepatic synthetic function. PT measures the rate of conversion of prothrombin to thrombin. To standardize the reporting of PT and avoid interlaboratory variability, the INR was developed. The INR is the ratio of the patient’s PT to the mean control PT. Because vitamin K is involved in the γ-carboxylation of factors used to measure PT (factors II, VII, IX, and X), values also may be prolonged in other conditions such as vitamin K deficiency and warfarin therapy.

**Cholestasis**

Cholestasis is a condition in which bile flow from the liver to the duodenum is impaired. Disturbances in bile flow may be due to intrahepatic causes (hepatocellular dysfunction) or extrahepatic causes (biliary tree obstruction). Cholestasis often results in the release of certain enzymes and thus can be detected by measuring the serum levels of bilirubin, AP, and GGT. Bilirubin is a breakdown product of hemoglobin metabolism. Unconjugated bilirubin is insoluble and thus is transported to the liver bound to albumin. In the liver, it is conjugated to allow excretion in bile. Measured total bilirubin levels can be normal or high in patients with significant liver disease because of the liver’s ability to conjugate significant amounts of bilirubin. Thus, to help aid in the diagnosis of hyperbilirubinemia, fractionation of total bilirubin is usually performed to distinguish between conjugated (direct) and unconjugated (indirect) bilirubin. Indirect bilirubin is a term frequently used to refer to unconjugated bilirubin in the circulation because the addition of another chemical is necessary to differentiate this fraction from the whole. Normally, >90% of serum bilirubin is unconjugated. The testing process for conjugated bilirubin, in contrast, is direct without the addition of other agents. The direct bilirubin test measures the levels of conjugated bilirubin and 8 bilirubin (conjugated bilirubin bound to albumin).

The patterns of elevation of the different fractions of bilirubin provide important diagnostic clues as to the cause of cholestasis. In general, an elevated indirect bilirubin level suggests intrahepatic cholestasis, and an elevated direct bilirubin level suggests extrahepatic obstruction. Mechanisms that can result in increases in unconjugated bilirubin levels include increased bilirubin production (hemolytic disorders and resorption of hematomas) or defects (inherited or acquired) in hepatic uptake or conjugation. The rate-limiting step in bilirubin metabolism is the excretion of bilirubin from hepatocytes, so conjugated hyperbilirubinemia can be seen in inherited or acquired disorders of intrahepatic excretion or extrahepatic obstruction. Conjugated bilirubin that cannot be excreted accumulates in hepatocytes, which results in its secretion into the circulation. Because conjugated bilirubin is water soluble, it can be found in the urine of patients with jaundice.

AP is an enzyme with a wide tissue distribution but is found primarily in the liver and bones. In the liver, it is expressed by the bile duct epithelium. In conditions of biliary obstruction, levels rise as a result of increased synthesis and release into the serum. Because the half-life of serum AP is approximately 7 days, it may take several days for levels to normalize even after resolution of the biliary obstruction.

GGT is another enzyme found in hepatocytes and released from the bile duct epithelium. Elevation of GGT is an early marker and also a sensitive test for hepatobiliary disease. Like AP elevation, however, it is nonspecific and can be produced by a variety of disorders in the absence of liver disease. Increased levels of GGT can be induced by certain medications, alcohol abuse, pancreatic disease, myocardial infarction, renal failure, and obstructive pulmonary disease. For this reason, elevated GGT levels are often interpreted in conjunction with other enzyme abnormalities. For example, a raised GGT level with increased AP level supports a liver source.

**Jaundice**

Jaundice refers to the yellowish staining of the skin, sclera, and mucous membranes with the pigment bilirubin. Hyperbilirubinemia usually is detectable as jaundice when blood levels rise above 2.5 to 3 mg/dL. Jaundice can be caused by a wide range of benign and malignant disorders. However, when present, it may indicate a serious condition, and thus knowledge of the differential diagnosis of jaundice and a systematic approach to the workup of the patient is necessary. Workup of a patient with jaundice is simplified by organizing the possible causes of the disorder into groups based on the location of bilirubin metabolism. As mentioned previously, bilirubin metabolism can take place in three phases: prehepatic, intrahepatic, and posthepatic.
The prehepatic phase includes the production of bilirubin from the breakdown of heme products and its transport to the liver. The majority of the heme results from red blood cell metabolism and the rest from other heme-containing organic compounds such as myoglobin and cytochromes. In the liver, the insoluble unconjugated bilirubin is then conjugated to glucuronic acid to allow for solubility in bile and excretion. The posthepatic phase of bilirubin metabolism consists of excretion of soluble bilirubin through the biliary system into the duodenum. Dysfunction in any of these phases can lead to jaundice.

**Prehepatic.** Jaundice as a result of elevated levels of unconjugated bilirubin occurs from faulty prehepatic metabolism and usually arises from conditions that interfere with proper conjugation of bilirubin in the hepatocyte. Insufficient conjugation is often seen in processes that result in excessive heme metabolism. Subsequently, the conjugation system is overwhelmed, which results in unconjugated hyperbilirubinemia.

Causes of hemolysis include inherited and acquired hemolytic anemias. Inherited hemolytic anemias include genetic disorders of the red blood cell membrane (hereditary spherocytosis and elliptocytosis), enzyme defects (glucose-6-phosphate dehydrogenase deficiency), and defects in hemoglobin structure (sickle cell anemia and thalassemias). Hemolytic anemias can also be acquired, and these can be further divided into those with immune-mediated and those with non–immune-mediated causes. Immune-mediated hemolytic anemias result in a positive finding on a direct Coombs’ test and have a variety of autoimmune and drug-induced causes. In contrast, direct Coombs’ test results are negative in nonimmune hemolytic anemias. The causes in this latter category are varied and include drugs and toxins that directly damage red blood cells, mechanical trauma (heart valves), microangiopathy, and infections. Prehepatic dysfunction of bilirubin metabolism also can result from failure in the transport of unconjugated bilirubin to the liver by albumin in any condition that leads to plasma protein loss. A poor nutritional state or excess protein loss as seen in burn patients can lead to elevated levels of unconjugated bilirubin in the circulation and jaundice.

**Intrahepatic.** Intrahepatic causes of jaundice involve the intracellular mechanisms for conjugation and excretion of bile from the hepatocyte. The enzymatic processes in hepatocytes can be affected by any condition that impairs hepatic blood flow and subsequent function of the liver (ischemic or hypoxic events). Furthermore, there are multiple inherited disorders of enzyme metabolism that can result in either unconjugated or conjugated hyperbilirubinemia. Gilbert’s syndrome is a genetic variant characterized by diminished activity of the enzyme glucuronyltransferase, which results in decreased conjugation of bilirubin to glucurone. It is a benign condition that affects approximately 4% to 7% of the population. Typically, the disease results in transient mild increases in unconjugated bilirubin levels and jaundice during episodes of fasting, stress, or illness. These episodes are self-limited and usually do not require further treatment. Another inherited disorder of bilirubin conjugation is Crigler-Najjar syndrome. It is a rare disease found in neonates and can result in neurotoxic sequelae from bilirubin encephalopathy.

In addition to defects in conjugation, disorders in bilirubin excretion in hepatocytes can also lead to jaundice. Rotor’s syndrome and Dubin-Johnson syndrome are two uncommon genetic disorders that disrupt secretion of conjugated bilirubin from the hepatocyte into the bile and result in conjugated hyperbilirubinemia. There are also multiple acquired conditions that result in inflammation and intrahepatic cholestasis by affecting hepatocyte mechanisms for conjugation and excretion of bile. Viruses, alcohol abuse, sepsis, and autoimmune disorders all can result in inflammation in the liver with subsequent disruption of bilirubin transport in the liver. In addition, jaundice can also occur from the cytotoxic effects of many medications, including acetaminophen, oral contraceptives, and anabolic steroids.

**Posthepatic.** Posthepatic causes of jaundice are usually the result of intrinsic or extrinsic obstruction of the biliary duct system that prevents the flow of bile into the duodenum. There is a wide spectrum of pathologies that may present with obstructive jaundice. Intrinsic obstruction can occur from biliary diseases, including cholelithiasis, choledocholithiasis, benign and malignant biliary strictures, cholangiocarcinoma, cholangitis, and disorders of the papilla of Vater. Extrinsic compression of the biliary tree is commonly due to pancreatic disorders. Patients with pancreatitis, pseudocysts, and malignancies can present with jaundice due to external compression of the biliary system. Finally, with the growing armamentarium of endoscopic tools and minimally invasive surgical approaches, surgical complications are becoming more frequent causes of extrahepatic cholestasis. Misadventures with surgical clips, retained stones, and inadvertent ischemic insults to the biliary system can result in obstructive jaundice recognized at any time from immediately postoperatively to many years later.

**RADIOLOGIC EVALUATION OF THE LIVER**

**Ultrasound** Abdominal ultrasound is a commonly applied imaging modality used to evaluate abdominal symptoms. Ultrasound technology is based on the pulse-echo principle. The ultrasound transducer converts electrical energy to high-frequency sound energy that is transmitted into tissue. Although some of the ultrasound waves are transmitted through the tissue, some are reflected back, and the ultrasound image is produced when the ultrasound receiver detects those reflected waves. This real-time gray scale (B-mode) imaging is augmented by Doppler flow imaging. Doppler ultrasound not only can detect the presence of blood vessels but also can determine the direction and velocity of blood flow. Ultrasonography is a useful initial imaging test of the liver because it is inexpensive, widely available, involves no radiation exposure, and is well tolerated by patients. It is excellent for diagnosing biliary pathology and focal liver lesions. In addition, liver injury can be evaluated in trauma patients using the focused abdominal sonography for trauma examination. Limitations of ultrasound include incomplete imaging of the liver, most often at the dome or beneath ribs on the surface, and incomplete visualization of lesion boundaries. Moreover, obesity and overlying bowel gas also can interfere with image quality. Thus, ultrasonographically detected masses usually require further evaluation by other imaging modalities due to the lower sensitivity and specificity of ultrasound compared with CT and MRI.

The advent of contrast-enhanced ultrasound has improved the ability of this modality to differentiate among benign and malignant lesions. The injection of gas microbubble agents can increase the sensitivity and specificity of ultrasound in detecting and diagnosing liver lesions. Microbubbles are <10 μm
and, when given intravenously, allow for more effective echo enhancement. Contrast-enhanced ultrasound imaging of the liver improves delineation of liver lesions through identification of dynamic enhancement patterns and the vascular morphology of the lesion. In addition, some agents exhibit a late liver-specific phase in which the bubbles are taken up by cells in the reticuloendothelial system and accumulate in normal liver parenchyma after the vascular enhancement has faded.

The use of intraoperative ultrasound of the liver has rapidly expanded over the years with the increasing number and complexity of hepatic resections being performed. It has the ability to provide the surgeon with real-time accurate information useful for surgical planning. Intraoperative ultrasound is considered the gold standard for detecting liver lesions, and studies have shown that it can identify 20% to 30% more lesions than other preoperative imaging modalities. Importantly, it has been shown to influence surgical management in almost 50% of planned liver resections for malignancies. Applications for intraoperative ultrasound of the liver include tumor staging, visualization of intrahepatic vascular structures (Fig. 31-10), and guidance of resection plane by assessment of the relationship of a mass to the vessels. In addition, biopsy of lesions and ablation of tumors can be guided by intraoperative ultrasound.

Ultrasound elastography, also referred to as transient elastography, can be used to assess the degree of fibrosis or cirrhosis in the liver. Low-frequency vibrations transmitted through the liver induce an elastic shear wave that is detected by pulse-echo ultrasonography as the wave propagates through the liver. The velocity of the wave correlates with the stiffness of the organ—the wave travels faster through fibrotic or cirrhotic tissues. Ultrasound elastography has been found in large cohorts of individuals to have a sensitivity of 87% and a specificity of 91% for the diagnosis of cirrhosis when compared with liver biopsy. Unlike liver biopsy, ultrasound elastography is non-invasive and can be repeated often without additional risk to the patient. Furthermore, this rapid test can acquire information from a larger area of the tissue relative to needle biopsy, providing a better understanding of the entire hepatic parenchyma and reducing sampling error.

**Computed Tomography**

CT produces a digitally processed cross-sectional image of the body from a large series of x-ray images. The introduction of helical (spiral) CT has improved the imaging capabilities of this technique compared to earlier conventional axial CT by combining a continuous patient-table motion with continuous rotation of the CT gantry and allowing rapid acquisition of a volume of data within a single breath hold. With the recent advent of multi-detector row CT scanners, high-resolution images can be obtained in submillimeter section thickness within a short scan time, with virtually no penalty in increased radiation dose. Together, these technological advances have led to reduced motion artifacts due to variations in inspiration, facilitated optimal contrast delivery, and allowed for the capability to generate high-resolution reformations in any desired plane. In a single examination, modern-day CT scans provide detailed morphologic information on the number, size, distribution, and vascularity of liver lesions, all of which are vital in guiding the clinical management and therapeutic plan.

Contrast medium is routinely used in CT evaluation of the liver because of the similar densities of most pathologic liver masses and normal hepatic parenchyma. A CT scan with a dual- or triple-phase bolus of intravenous contrast agent is performed to achieve the greatest enhancement of contrast between normal and pathologic tissues. Ideally, contrast media should be selectively delivered to either the tumor or the liver, but not both. Radiologists use the dual blood supply of the liver and the hemodynamics of hepatic tumors to achieve this goal. The liver is unique in that it has a dual blood supply. As previously noted, the portal vein supplies approximately 75% of the blood flow and the hepatic artery the remaining 25%. However, many liver tumors receive the majority of their blood supply from the hepatic artery. After injection of the contrast agent, the rapid
scan time of helical CT allows for CT sections through the liver in both the arterial dominant phase (20 to 30 seconds after the beginning of contrast delivery) and venous or portal dominant phase (60 to 70 seconds after contrast injection) (Fig. 31-11). Thus, many hepatic tumors that derive the majority of their blood supply from the hepatic artery as well as other hypervascular lesions are well delineated in the arterial phase. On the other hand, the portal phase provides optimal enhancement of the normal liver parenchyma because the majority of its blood supply is derived from the portal vein. This allows for detection of hypovascular lesions because they will appear hypointenated in relation to the brighter normal liver parenchyma. Furthermore, the arterial and portal phase images allow for noninvasive mapping of the hepatic arterial and venous anatomy, information that is crucial in the preoperative planning for patients undergoing liver surgery.

CT cholangiography has emerged as a new imaging modality for biliary disease. This technique usually involves the use of contrast agents, which are excreted by hepatocytes into the bile ducts. CT cholangiography, therefore, provides information on hepatocyte function and bile flow, in addition to high-resolution depiction of the biliary tree. It has compared well to endoscopic retrograde cholangiopancreatography (ERCP) in identifying obstructive biliary disease. One of the major advantages of CT cholangiography over other imaging modalities is the ability to depict small nondilated peripheral biliary radicals. This technique may be useful in the context of live liver donation or complex biliary surgery to aid in the preoperative depiction of biliary anatomy. It also may be applicable in the postoperative setting for the detection of biliary leakage or obstruction. A limitation of CT cholangiography is that the biliary tree may not be well visualized in patients with excessively dilated bile ducts or in those with hyperbilirubinemia, as bilirubin excretion is impaired in these cases.

### Magnetic Resonance Imaging

MRI is a technique that produces images based on magnetic fields and radio waves. The MRI scanner creates a powerful magnetic field that aligns the hydrogen atoms in the body, and radio waves are used to alter the alignment of this magnetization. Different tissues absorb and release radio wave energy at different rates, and this information is used to construct an image of the body. Most tissues can be differentiated by differences in their characteristic T1 and T2 relaxation times. T1 is a measure of how quickly a tissue can become magnetized, and T2 measures how quickly it loses its magnetization. As with CT technology, advances in MRI now provide the opportunity to perform single-breath T1-weighted imaging and respiration-triggered T2-weighted imaging. The development of breath-hold imaging techniques has eliminated many of the motion artifacts that previously limited the sensitivity and application of MRI for imaging of the liver. Compared with CT scanning, the major advantages of MRI pertain to higher soft tissue contrast resolution and excellent depiction of fluid-containing structures, while obviating the need for ionizing radiation.

As with the iodinated contrast media use in CT scanning, multiple contrast agents have been developed for MRI to increase the difference in signal intensity between normal liver and pathologic lesions. Various gadolinium-based compounds have been used as MRI contrast agents that behave in a manner very similar to iodine in CT. Liver-specific MRI contrast agents also have been developed that rely either on excretion by Kupffer cells, such as ferumoxide (Feridex, Advanced Magnetics, Cambridge, MA), or on secretion in bile by hepatocytes, including gadoxetate (Eovist or Primovist, Bayer-Schering, Berlin, Germany). These agents combine the information obtained during a standard MRI with additional functional data, which in turn yields improved detection and characterization of lesions within the liver.

Just as ultrasound elastography is useful in the diagnosis of hepatic fibrosis and cirrhosis, magnetic resonance (MR) elastography appears promising as an imaging modality in reducing the need for liver biopsy. In this technique, a vibration device is used to induce a shear wave in the liver. A modified MRI machine detects the shear wave, then generates a color-coded image that...
depicts the wave velocity, and hence stiffness, throughout the organ. Although preliminary studies have shown that MR elastography can detect cirrhosis with a high degree of accuracy, the clinical utility of this modality, especially given its relatively high cost, remains to be determined.

Magnetic resonance cholangiopancreatography (MRCP) enables rapid, noninvasive depiction of both the biliary tree and the pancreatic duct without the use of ionizing radiation or intravenous contrast media. One of the most common clinical indications for MRCP is biliary obstruction. MRCP provides visualization of dilated bile ducts, and the high spatial and contrast resolution often enables accurate assessment of the level of occlusion in the biliary tree. MRCP also can be enhanced with liver-specific MRI contrast agents that are actively secreted into the bile, but the clinical indications for such studies are still a matter of intensive investigation.

**Positron Emission Tomography**

Positron emission tomography (PET) is a nuclear medicine test that produces images of metabolic activity in tissues by detecting gamma rays emitted by a radioisotope incorporated into a metabolically active molecule. Fluorodeoxyglucose (FDG) is the most common metabolic molecule used in PET imaging. Although traditional imaging such as CT, ultrasound, and MRI provide anatomic information, PET offers functional imaging of tissues with high metabolic activity, including most types of metastatic tumors. PET imaging increasingly is used as a tool in the diagnostic evaluation of patients with potentially resectable metastatic tumors. PET imaging is particularly useful in the detection of both intraperitoneal and extraperitoneal disease. In nonrandomized trials, PET demonstrated better sensitivity and specificity than CT scanning for the detection of both intrahepatic and extraperitoneal disease. Integrated PET/CT improves diagnostic accuracy over standard PET or CT alone and has been shown to be sensitive in the detection of liver metastases derived from a wide range of cancers, including colorectal (Fig. 31-12), breast, or lung primaries.

More than 20% of patients with colorectal cancer initially present with hepatic metastasis, and a large percentage of patients undergoing resection for their primary colorectal cancer eventually experience disease recurrence in the liver. The role of FDG-PET/CT in colorectal cancers lies predominantly in tumor staging and follow-up, particularly in the detection of occult intrahepatic metastases or extraperitoneal disease. Although hepatic resection of colorectal metastases provides survival rates nearing 50%, the presence of extrahepatic disease is a poor prognosticator and usually precludes aggressive surgical intervention. Thus, accurate information regarding the extent of the disease is necessary for management of patients with colorectal metastases. PET/CT has also been shown to be more accurate than contrast-enhanced CT in tumor surveillance after radiofrequency ablation. The sensitivity of FDG-PET, however, is lowered by neoadjuvant chemotherapy, most likely secondary to reduced metabolic activity within the tumor.

Although the role of PET/CT in the clinical management of liver metastases has been well-established, its utility in the diagnostic workup of primary liver tumors is still debated. In hepatocellular carcinoma (HCC), FDG uptake correlates with the degree of differentiation—high-grade HCC lesions have increased FDG uptake compared to low-grade HCCs. As a result, the overall sensitivity of FDG-PET/CT in the detection of HCCs is reported to be only 50% to 65%, rendering this modality insufficient when used alone in the diagnosis of primary HCCs. For this reason, dual-tracer PET has been introduced to improve sensitivity in detecting all HCC. This modality combines the use of FDG, which accumulates in poorly differentiated tumors, with T1-acetate, a tracer preferentially accumulated by well-differentiated HCC lesions. Although the clinical benefits of dual-tracer PET/CT have yet to be fully established, this combined modality has the potential to become a valuable tool in the diagnosis and staging of HCC. In cholangiocarcinoma tumors, FDG avidity depends on the morphologic characteristics and location of the lesion. Therefore, FDG-PET and FDG-PET/CT have not been shown to be highly beneficial in the diagnosis of primary cholangiocarcinoma, but they may be beneficial in the detection of regional and distal metastases, which can affect clinical decision making and patient management.

**ACUTE LIVER FAILURE**

Acute liver failure (ALF) occurs when the rate and extent of hepatocyte death exceeds the liver’s regenerative capabilities. It was initially described as a specific disease entity in the 1950s. It also has been referred to as fulminant hepatic failure. ALF is a rare disorder affecting approximately 2000 patients annually in the United States. ALF is defined by the development of hepatic encephalopathy occurring within 26 weeks of severe liver injury in a patient without a history of previous liver disease or portal

---

**Figure 31-12.** Computed tomography (CT)–positron emission tomography (PET) scans before and after resection of liver metastasis from colorectal cancer in a 54-year-old patient. CT scan shows large 10-cm right lobe liver metastasis (left panel), and PET scan findings are strongly positive (middle panel). Two years after right hepatectomy, the patient has no evidence of recurrence and significant hypertrophy of the left lobe (right panel).
The manifestations of ALF may include cerebral edema, hemodynamic instability, increased susceptibility to bacterial and fungal infections, renal failure, coagulopathy, and metabolic disturbances. Even with current medical care, ALF can progress rapidly to hepatic coma and death. The most common cause of death is intracranial hypertension due to cerebral edema, followed by sepsis and multisystem organ failure.

The causes of ALF, which are the most important variables in determining outcome, are numerous and can include viral infection as well as drug overdose, reaction, and toxicity. It has been determined that the etiologic factor leading to ALF varies according to geographic location. Before the introduction of orthotopic liver transplantation (OLT), the chance for survival was <20%. Currently, most series report 5-year survival rates of >70% for affected patients.

### Etiology

Differences in etiology, management, and patient outcomes have been described for various regions of the globe. In the East and developing portions of the world, the most common causes of ALF are viral infections, primarily hepatitis B, A, and E. In these areas, there are a relatively small number of drug-induced cases. In contrast, 65% of cases of ALF in the West are thought to be due to drugs and toxins, with acetaminophen (paracetamol) being the most common etiologic agent in the United States, Australia, United Kingdom, and most of Europe. In France and Spain, where acetaminophen sales are restricted, the rate of acetaminophen-induced ALF is quite low. Acetaminophen-induced ALF is also uncommon in South America. The U.S. Acute Liver Failure Study Group identified several other causes of ALF, including autoimmune hepatitis, hypoperfusion of the liver (in cardiomyopathy or cardiogenic shock), pregnancy-related conditions, and Wilson’s disease. Even with exhaustive efforts to identify a cause, approximately 20% of all cases of ALF remain indeterminate in origin.

### Clinical Presentation

In a multicenter study involving 17 tertiary care centers and 308 patients in the United States, 73% of all patients with ALF were female, with a median age of 38 years. The most common ethnic group affected was whites (74%), followed by Hispanics (9%) and African Americans (3%). Patients were ill for a median of 6 days before the onset of encephalopathy and had a median of 2 days between the onset of jaundice and the development of encephalopathy. Hepatic coma grade at presentation was approximately equally distributed across grades I to IV. Eighty-four percent of the patients in the study were referred from outside hospitals, 40% had a serum creatinine level exceeding 2.0 mg/dL, and 14% had an arterial pH of <7.30. In addition, 44% of the patients acquired a culture-proven infection.

### Diagnosis and Clinical Management

When the medical history is obtained, it is important to address the possibility of exposure to viral infections, medications, and other possible toxins. The possibility of previous liver disease needs to be explored. The physical examination must assess and document the patient’s mental status as well as attempt to identify findings of chronic liver disease. The initial laboratory examination must evaluate the severity of the ALF as well as attempt to identify the cause (Table 31-1). A liver biopsy should be performed if certain disease entities such as autoimmune hepatitis or lymphoma are a possibility. Because of the associated coagulopathy, if a liver biopsy is needed, it is usually safest to obtain the tissue via a transjugular approach. Patients with ALF should be admitted to the hospital and monitored frequently. Due to the rapidity with which this disease process may progress, a liver transplant center should be contacted and the affected patient transferred to the center early in the evaluation period.

If acetaminophen overdose is suspected to have occurred within a few hours of presentation, administration of activated charcoal may be useful to reduce the volume of acetaminophen present in the gastrointestinal (GI) tract. N-acetylcysteine (NAC), the clinically effective antidote for acetaminophen overdose, should be administered as early as possible to any patient with suspected acetaminophen-associated ALF. NAC also should be administered to patients with ALF of unclear etiology, because replenishing glutathione may be beneficial in this patient population as well. NAC can be administered either orally (140 mg/kg initial dose, followed by 70 mg/kg every 4 hours × 17 doses) or via the intravenous route (loading dose of 150 mg/kg, followed by a maintenance dose of 50 mg/kg every 4 hours × 12 doses). For patients who are suspected of having drug-induced hepatotoxicity, it is important to obtain details regarding all prescription and nonprescription drugs, herbs, and dietary supplements that may have been taken in the previous year. Most instances of drug-induced hepatotoxicity occur in the first 6 months after drug initiation. Any suspected offending agent must be discontinued, and an attempt should be made to administer only essential medications.

The majority of patients with ALF need to be monitored in the intensive care unit (ICU) setting, and specific attention needs to be given to fluid management, ulcer prophylaxis, hemodynamic monitoring, electrolyte management, and surveillance for and treatment of infection. Surveillance cultures should be performed to identify bacterial and fungal infections as early as possible. Serum phosphorus levels need to be monitored. Hypophosphatemia, a sign of hepatic regeneration, may indicate a higher likelihood of spontaneous recovery and needs to be corrected via intravenous (IV) administration of phosphate. Sedation should be avoided, and the head of the bed should be elevated at least 30°. Neurologic examinations

HIV = human immunodeficiency virus.
should be performed frequently. Intracranial pressure monitoring is reserved for patients in whom a neurologic examination is no longer reliable. CT scans of the head should be performed to rule out mass lesion or hemorrhage, but they provide only limited information regarding increased intracranial pressure. The administration of blood products for thrombocytopenia and prolonged PT is recommended only in the setting of hemorrhage or before invasive procedures. Acute renal failure is a frequent complication in patients with ALF, and efforts should be made to protect renal function by maintaining sufficient perfusion and avoiding nephrotoxic medications. Should renal replacement therapy become necessary, continuous venous hemodialysis should be used rather than intermittent hemodialysis, because continuous venous hemodialysis provides better hemodynamic and intracranial pressure stability. The most severely affected patients have a poor prognosis with medical management alone and require liver transplantation. Identifying these patients early in the clinical course is important both to maximize the time available to obtain a donor liver allograft for those in need and to avoid transplant in those who will recover without it.

**Prognosis**

Accurate identification of ALF patients who will recover spontaneously is important because of the severe shortage of donor liver allografts and the potential complications of lifelong nonspecific immunosuppression. The most widely applied prognostic scoring system is the King’s College Hospital ALF criteria. This scoring system has separate criteria predicting a poor medical management outcome for acetaminophen-related and non-acetaminophen-related forms of ALF (Table 31-2). Many other prognostic models exist such as the Acute Physiology and Chronic Health Evaluation II (APACHE II) score, the Clichy criteria, and actin-free Gc-globulin serum concentration. Overall, prognostic scoring systems have proven to have acceptable specificity but low sensitivity in determining patient outcome and therefore should not replace the judgment of an experienced clinician.

**Liver Transplantation**

Despite advances in medical management, OLT remains the only definitive therapy for patients unable to regenerate sufficient hepatocyte mass in a timely manner. The advent of OLT has coincided with a rise in overall ALF survival rates from approximately 20% in the pretransplantation era to >70% at the present time. One-year posttransplantation survival for patients with ALF has been reported to be as high as 80% to 90%. Although these improvements in survival rates are impressive, it should be noted that 10% of patients still die while awaiting OLT, which confirms that the potential for improved patient outcome still has not been realized because of the ongoing liver allograft shortage.

**Emerging Technologies**

As mentioned earlier, patient survival could be improved if additional time could be gained for the patient while awaiting liver replacement or hepatocyte regeneration. The development of a support device to replace the acutely failing liver has been a highly sought after (and elusive) goal. Several systems have been tested without definitive evidence of efficacy. Transient improvement in hepatic encephalopathy has been observed in several trials, but improvement in hepatocyte function and long-term benefit have not been realized. Liver support trials are difficult to perform due to access to liver replacement, the rarity of affected patients, and the heterogeneous causes and varying levels of disease severity. Therefore, additional data are necessary, and liver support systems should be used only as part of an approved clinical trial. Focus has now shifted toward xenotransplantation, organ engineering, and cell transplantation. In the meantime, living donation and auxiliary liver transplantation can help overcome the organ shortage.

**CIRRHOSIS AND PORTAL HYPERTENSION**

Cirrhosis, the final sequela of chronic hepatic insult, is characterized by the presence of fibrous septa throughout the liver subdividing the parenchyma into hepatocellular nodules (Fig. 31-13). Cirrhosis is the consequence of sustained wound healing in response to chronic liver injury. Approximately 40% of cirrhotic patients are asymptomatic, but progressive deterioration leading to the need for liver transplantation or death is typical after the development of end-stage liver disease (ESLD). The complications of ESLD include progressive hyperbilirubinemia, malnutrition, decreased synthetic function of the liver, coagulopathy, portal hypertension (i.e., ascites and variceal bleeding), hepatic encephalopathy, and life-limiting fatigue. ESLD carries a 5-year mortality of 50%, with 70% of deaths due to liver failure. In the United States, cirrhosis accounts for 30,000 deaths per year and is the most common nonneoplastic cause of death among patients with hepatobiliary and digestive diseases. An additional 10,000 to 12,000 deaths occur annually due to HCC, the most rapidly increasing neoplasm in the United States.

**Morphologic Classification of Cirrhosis**

Morphologically, cirrhosis can be described as micronodular, macronodular, or mixed. Micronodular cirrhosis is characterized by thick regular septa, small uniform regenerative nodules, and involvement of virtually every hepatic lobule. Macronodular cirrhosis frequently has septa and regenerative nodules of...
varying sizes. The regenerative nodules consist of irregularly sized hepatocytes with large nuclei and cell plates of varying thickness. Mixed cirrhosis is present when regeneration is occurring in a micronodular liver and over time converts to a macronodular pattern. This morphologic categorization is limited, and cirrhosis is a dynamic process in which nodule size varies over time. The three patterns correlate poorly with etiology, and the same pattern can result from a variety of disease processes. Conversely, a single disease process can demonstrate several morphologic patterns. Irrespective of etiology and morphologic pattern, the cirrhotic liver frequently demonstrates right hepatic lobe atrophy, caudate lobe and left lateral segment hypertrophy, recanalization of the umbilical vein, a nodular surface contour, dilatation of the portal vein, gastroesophageal varices, and splenomegaly on radiographic evaluation.

**Etiology of Cirrhosis**

Cirrhosis can result from a wide range of disease processes, including viral, autoimmune, drug-induced, cholestatic, and metabolic diseases (Table 31-3). In the diagnosis of alcoholic liver disease, documentation of chronic alcohol abuse is imperative. Liver biopsy will reveal the typical findings of alcoholic hepatitis, including hepatocyte necrosis, Mallory bodies, neutrophil infiltration, and perivenular inflammation. Patients with nonalcoholic steatohepatitis (NASH) often endorse a history of diabetes mellitus or metabolic syndrome. The diagnosis of NASH requires the demonstration of steatohepatitis on biopsy, the lack of a history of significant alcohol consumption, and exclusion of other causes of hepatic steatosis. Although cryptogenic cirrhosis, or cirrhosis without an apparent cause, accounted for a third of all cases in the past, this proportion has declined over time as it becomes increasingly apparent that many of such patients may actually have unrecognized NASH.

Chronic hepatitis C infection is the most common cause of chronic liver disease and the most frequent indication for liver transplantation in the United States. The identification of chronic hepatitis C infection is facilitated by serologic assays that detect antibody to hepatitis C and molecular assays that quantify hepatitis C viral RNA. Chronic hepatitis B, on the other hand, can be diagnosed based on the detection of hepatitis B surface antigen (HBsAg) more than 4 to 6 months after initial infection. Additional tests of hepatitis B viral replication, such as the hepatitis B e antigen (HBeAg) and hepatitis B viral DNA, can be used to confirm ongoing infection and to guide appropriate antiviral therapy.

Autoimmune causes of cirrhosis include primary biliary cirrhosis, primary sclerosing cholangitis, and autoimmune hepatitis. Patients with primary biliary cirrhosis may be asymptomatic or may present with a history of fatigue, pruritus, and skin hyperpigmentation that is not related to jaundice. Antimitochondrial antibodies will test positive in the vast majority of cases. Affected patients also may have marked elevations in serum cholesterol, while hyperbilirubinemia is seen late in the course of the disease. Primary sclerosing cholangitis is a chronic cholestatic disease of the liver associated with ulcerative colitis and Crohn’s disease. The clinical presentation can include pruritus, steatorrhea, fat-soluble vitamin deficiencies, and metabolic bone disease. The diagnosis is often established by imaging of the biliary tree, which reveals a characteristic picture of diffuse, multifocal strictures with focal dilation of the bile ducts resulting in a beaded appearance. Complications are common and can include biliary strictures, cholangitis, cholelithiasis, and

Clinical Manifestations of Cirrhosis

The clinical history associated with cirrhosis can include fatigue, anorexia, weight loss, jaundice, abdominal pain, peripheral edema, ascites, GI bleeding, and hepatic encephalopathy. On physical examination, a number of findings have been described in patients with cirrhosis. Spider angioma and palmar erythema are believed to be caused by alterations in sex hormone metabolism. Finger clubbing may be a consequence of hypoproteinemia, while the pathogenesis of white nail beds and Dupuytren’s contractures are less well understood. Males may develop features of feminization such as gynecomastia, loss of chest and axillary hair, and testicular atrophy. Splenomegaly is common, whereas the cirrhotic liver itself may be enlarged, normal sized, or small. Ascites and pleural effusion can be seen with fluid accumulation. Portal hypertension can manifest as caput medusae and/or the presence of the Cruveilhier-Baumgarten murmur, a venous hum that can be auscultated in the epigastrium resulting from collaterals between the portal system and the remnant of the umbilical vein. Jaundice usually does not appear until the bilirubin rises above 2 to 3 mg/dL. Asterixis can be detected in patients with hepatic encephalopathy. Other manifestations include fetor hepaticus, as well as features suggestive of malnutrition such as weakness, weight loss, and temporal muscle wasting.

Although fat stores and muscle mass are reduced, resting energy expenditure is increased. Muscle cramps occur frequently in the cirrhotic patient and are felt to correlate with ascites, low mean arterial pressure, and plasma renin activity. Abdominal hernias are common with ascites and should be electively repaired only in patients with well-compensated cirrhosis; otherwise, the hernia should be repaired at the time of or after hepatic transplantation. HCC can occur in all forms of cirrhosis, and every cirrhotic patient should undergo screening for the development of HCC every 6 months via imaging and measurement of a serum α-fetoprotein (AFP) level. Cirrhosis is associated with increased cardiac output and heart rate as well as decreased systemic vascular resistance and blood pressure. Patients with cirrhosis are more prone to infections due to impaired phagocytic activity of the reticuloendothelial system. Bacterial infections, often of intestinal origin, are common and must be suspected in a patient with unexplained pyrexia or clinical deterioration. Spontaneous bacterial peritonitis also is seen in cases of cirrhosis with ascites. Intrinsic drug metabolism is reduced in the cirrhotic liver, and this fact needs to be recognized when prescribing medications.

Risk in the Cirrhotic Patient

Assessing the hepatic reserve of the cirrhotic patient is important, because cirrhosis and portal hypertension can have a negative impact on the outcome of nontransplant surgical procedures. Patients with liver disease undergoing surgery are at increased risk for surgical and anesthesia-related complications. The actual risk depends on the type of anesthetic used, the specific surgical procedure performed, and the severity of liver disease. Previous studies have demonstrated that emergency operations, cardiac surgery, hepatic resections, and abdominal surgery, particularly cholecystectomy, gastric resection, and colectomy, generate the highest operative risk among cirrhotic patients. Additionally, preoperative patient characteristics such as anemia, ascites, encephalopathy, malnutrition, hypoalbuminemia, hypoxemia, infection, jaundice, portal hypertension, and prolonged PT have also been associated with inferior outcomes after surgery. Nontransplant surgical procedures are contraindicated in patients with acute fulminant hepatitis and those with severe decompensated chronic hepatitis.

A number of laboratory tests have been used to assess hepatic reserve in patients with cirrhosis. Tests of indocyanine green, sorbitol, and galactose elimination capacity as well as the carbon-13 galactose breath test and carbon-13 aminopyrine breath test have all been disappointing clinically due to their
dependence on flow to the liver as well as the unavailability and complexity of the tests. The monoethylglycinexylidide (MEGX) test, which measures MEGX formation after the administration of lidocaine, has been shown to be approximately 80% sensitive and specific in diagnosing cirrhosis. However, this test loses both sensitivity and specificity as the serum bilirubin level rises and interferes with the fluorescent readout system.

Child-Turcotte-Pugh Score

The Child-Turcotte-Pugh (CTP) score was originally developed to evaluate the risk of portocaval shunt procedures performed for portal hypertension and subsequently has been shown to be useful in predicting surgical risks of other intra-abdominal operations on cirrhotic patients (Table 31-4). Numerous studies have demonstrated overall surgical mortality rates of 10% for patients with class A cirrhosis, 30% for those with class B cirrhosis, and 75% to 80% for those with class C cirrhosis. The CTP score is derived from five variables as shown in Table 31-4. The problems with the CTP score are the presence of subjective variables (encephalopathy and ascites), its narrow range (5 to 15 points), and the equal weighting given to each variable. Multiple retrospective studies have demonstrated that perioperative mortality and morbidity rates correlate well with the CTP score, and for over 30 years, this measure had been used as the principal predictor of operative risk.

Model for End-Stage Liver Disease Scoring System

The Model for End-Stage Liver Disease (MELD) is a linear regression model based on objective laboratory values (INR, bilirubin level, and creatinine level). It was originally developed as a tool to predict mortality after transjugular intrahepatic portosystemic shunt (TIPS) but has been validated and used as the sole method of liver transplant allocation in the United States since 2002. The MELD formula is as follows:

\[
\text{MELD Score} = 9.57 \ln(\text{SCr}) + 3.78 \ln(\text{Tbil}) + 11.2 \ln(\text{INR}) + 6.43
\]

where Ln represents natural logarithm, SCr is serum creatinine level (in milligrams per deciliter), and Tbil is serum bilirubin level (in milligrams per deciliter).

A number of studies have examined the relative values of MELD and CTP scores in predicting postoperative mortality in cirrhotic patients undergoing nontransplant surgical procedures. Nouthup and colleagues demonstrated that MELD score was the only statistically significant predictor of 30-day mortality. In this study, mortality increased by approximately 1% for each MELD point up to a score of 20 and by 2% for each MELD point above 20. A comparison of the MELD model with the CTP classification showed good correlation between the two measures in predicting mortality, especially in the setting of emergency surgery. In these studies, the relative risk of mortality increased by 14% for each 1-point increase in MELD score. As a result, it has been proposed that patients with a MELD score below 10 can safely undergo elective surgery, those with MELD between 10 and 15 may undergo surgery with caution, while those with MELD scores in excess of 15 should not be subjected to elective surgical procedures.

Portal Hypertension

The portal venous system contributes approximately 75% of the blood and 72% of the oxygen supplied to the liver. In the average adult, 1000 to 1500 mL/min of portal venous blood is supplied to the liver. However, this amount can be significantly increased in the cirrhotic patient. The portal venous system is without valves and drains blood from the spleen, pancreas, gallbladder, and abdominal portion of the alimentary tract into the liver. Tributaries of the portal vein communicate with veins draining directly into the systemic circulation. These collateral communications occur at the gastroesophageal junction, anal canal, falciform ligament, splenic venous bed and left renal vein, and retroperitoneum (Fig. 31-14). The normal portal venous pressure is 5 to 10 mmHg, and at this pressure, very little blood is shunted from the portal venous system into the systemic circulation. As portal venous pressure increases, however, the collateral communications with the systemic circulation dilate, and a large amount of blood may be shunted around the liver and into the systemic circulation.

Imaging of the Portal Venous System and Measurement of Portal Venous Pressure

The patency of the portal vein and the nature of the collateral circulation should be established. An understanding of portal vein patency and anatomy is crucial before undertaking portosystemic shunts, hepatic resection, or hepatic transplantation. The simplest initial investigation is abdominal ultrasonography. A large portal vein suggests portal hypertension but is not diagnostic. Doppler ultrasound is capable of outlining the anatomy of the portal vein, excluding the presence of thrombosis, and identifying the direction of portal venous blood flow. Doppler ultrasound also is useful in evaluating blood flow through surgical shunts and TIPS. Abdominal CT and magnetic resonance angiography both are capable of revealing portal vein anatomy as well as patency. Visceral angiography and portal venography are reserved for cases that cannot be evaluated satisfactorily by noninvasive methods and require further clarification of portal patency or anatomy.

The most accurate method of determining portal hypertension is hepatic venography. The most commonly used procedure involves placing a balloon catheter directly into the hepatic vein and measuring the free hepatic venous pressure (FHVP) with the balloon deflated and the wedged hepatic venous pressure (WHVP) with the balloon inflated to occlude the hepatic vein. The hepatic venous pressure gradient (HVPG) is then calculated by subtracting the free from the wedged venous pressure.

**Child-Turcotte-Pugh class**

- Class A = 5–6 points
- Class B = 7–9 points
- Class C = 10–15 points
The HVPG represents the pressure in the hepatic sinusoids and portal vein and is a measure of portal venous pressure. Clinically significant portal hypertension is evident when HVPG exceeds 10 mmHg.

**Etiology and Clinical Features of Portal Hypertension**

The causes of portal hypertension can be divided into three major groups: presinusoidal, sinusoidal, and postsinusoidal. Although multiple disease processes can result in portal hypertension (Table 31-5), in the United States, the most common cause of portal hypertension is usually an intrahepatic one, namely, cirrhosis. The most significant clinical finding associated with portal hypertension is the development of gastroesophageal varices, which are mainly supplied by the anterior branch of the left gastric (coronary) vein.

Portal hypertension also results in splenomegaly with enlarged, tortuous, and even aneurysmal splenic vessels. Splenomegaly is frequently associated with functional hypersplenism, causing leukopenia, thrombocytopenia, and anemia. Ascites occurs in the setting of severe portal hypertension in combination with hepatocyte dysfunction. The umbilical vein may recannulate and dilate, leading to visible collaterals on the abdominal wall. Anorectal varices are present in approximately 45% of cirrhotic patients and must be distinguished from hemorrhoids, which do not communicate with the portal system and are not present at increased incidence in patients with portal hypertension. Large spontaneous venous shunts may form between the portal venous system and the left renal vein or the IVC, but these shunts are ineffective in reducing portal venous pressures and preventing bleeding from gastroesophageal varices.

**Management of Gastroesophageal Varices**

The most significant manifestation and the leading cause of morbidity and mortality related to portal hypertension is variceal bleeding. Approximately 30% of patients with compensated cirrhosis and 60% of patients with decompensated cirrhosis have esophageal varices. One third of all patients with varices will experience variceal bleeding. Each episode of bleeding is associated with a 20% to 30% risk of mortality. If left untreated, 70% of patients who survive the initial bleed will experience recurrent variceal hemorrhage within 2 years of the index hemorrhage.

**Prevention of Variceal Bleeding**

Current measures aimed at preventing variceal bleeding include the administration of nonselective β-blockers and prophylactic

</table>
endoscopic surveillance with variceal band ligation. Meta-analyses have demonstrated that nonselective \( \beta \)-blockers such as propranolol and nadolol reduce the index variceal bleed by approximately 45% and decrease bleeding mortality by 50%. However, approximately 20% of patients do not respond to \( \beta \)-blockade, and another 20% cannot tolerate \( \beta \)-blockade due to medication side effects. Endoscopic surveillance with prophylactic variceal band ligation has been associated with a lower incidence of a first variceal bleed. Variceal band ligation is recommended for patients with medium to large varices, performed every 1 to 2 weeks until obliteration, followed by esophagogastroduodenoscopy (EGD) 3 months later and surveillance EGD every 6 months to monitor for recurrence of varices.

**Management of Acute Variceal Hemorrhage**

Patients with acute variceal hemorrhage should be admitted to an ICU for resuscitation and management. Blood resuscitation should be performed carefully to reach a hemoglobin level of approximately 8 g/dL. Overzealous replacement of blood products and administration of saline can lead to both rebleeding and increased mortality. Administration of fresh frozen plasma and platelets can be considered in patients with severe coagulopathy. Use of recombinant factor VIIa has not been shown to be more beneficial than standard therapy and therefore is not recommended at this time. Cirrhotic patients with variceal bleeding have a high risk of developing bacterial infections, which are associated with increased risks of rebleeding and mortality. Spontaneous bacterial peritonitis accounts for approximately half of these infections, with urinary tract infections and pneumonias comprising the remainder. The use of short-term prophylactic antibiotics (e.g., ceftriaxone 1 g/d intravenously) has been shown both to decrease the rate of bacterial infections and to increase survival.

Vasoactive medications decrease blood flow to the gastrointestinal varices and can be initiated as soon as the diagnosis of variceal bleeding is made. Although vasopressin is the most potent available vasoconstrictor, its use is limited by its systemic vasoconstrictive effects that can produce hypertension, myocardial ischemia, arrhythmias, ischemic abdominal pain, and limb gangrene. Octreotide, a somatostatin analog, has the advantage that it can be administered for 5 days or longer, and it is currently the preferred pharmacologic agent for initial management of acute variceal bleeding. In addition to pharmacologic therapy, endoscopy with variceal band ligation should be carried out as soon as possible. This combination of pharmacologic and endoscopic therapy has been shown both to improve the initial control of bleeding and to increase the 5-day hemostasis rate.

**Luminal Tamponade**

When medical and endoscopic measures fail to control variceal hemorrhage, balloon tamponade using a Sengstaken-Blakemore tube will control refractory bleeding in up to 90% of patients. However, its application is limited due to the potential for complications, which include aspiration, airway obstruction, and esophageal perforation due to overinflation or pressure necrosis. Therefore, the use of a Sengstaken-Blakemore tube should not exceed 36 hours to avoid tissue necrosis, and this treatment modality should only be considered a temporary bridge to more definitive measures of variceal hemorrhage control.

**Transjugular Intrahepatic Portosystemic Shunt**

The TIPS procedure involves implantation of a metallic stent between an intrahepatic branch of the portal vein and a hepatic vein radicle. The needle track is dilated until a portal pressure gradient of ≥12 mmHg is achieved. TIPS can be performed in 95% of patients with an experienced interventional radiologist, controls variceal bleeding in >90% of cases refractory to medical treatment, and should not affect subsequent hepatic transplantation. Possible complications include bleeding either intra-abdominally or via the biliary tree, infections, renal failure, decreased hepatic function, and hepatic encephalopathy, which occur in 25% to 30% of patients after the TIPS procedure. A high rate of thrombosis is seen and can be attributed to intimal hyperplasia of the metallic stent. Frequent follow-up with repeated interventions such as dilation or restenting often are needed to maintain TIPS patency.
the most difficult to perform. It requires division of the gastroesophageal collaterals and allows venous drainage of the stomach and lower esophagus through the short gastrosplenic veins into the spleen, and ultimately decompresses the left upper quadrant by allowing the splenic vein to drain directly into the left renal vein via an end-to-side splenic to left renal vein anastomosis. This shunt has the advantages of being associated with a lower rate of hepatic encephalopathy and decompensation and not interfering with subsequent liver transplantation.

Nonshunt Surgical Management of Refractory Variceal Bleeding
In the patient with extrahepatic portal vein thrombosis and refractory variceal bleeding, the Sugiura procedure may be considered. The Sugiura procedure consists of extensive devascularization of the stomach and distal esophagus along with transection of the esophagus, splenectomy, truncal vagotomy, and pyloroplasty. As with performance of surgical shunts, patient survival is dependent on hepatic reserve at the time of the surgical procedure. Experience in Western countries is somewhat limited, and a number of modifications have been made to the original Sugiura procedure over time.

Hepatic Transplantation
Patients with cirrhosis, portal hypertension, and variceal bleeding usually die as a result of hepatic failure and not acute blood loss. Therefore, hepatic transplantation must be considered in the patient with ESLD, because it represents the patient’s only chance for definitive therapy and long-term survival. Hepatic transplantation also can be considered for the patient with variceal bleeding refractory to all other forms of management. Survival after hepatic transplantation is not affected adversely by the previous performance of endoscopic variceal band ligation, TIPS, or splenorenal or mesocaval shunts. Previous creation of an Eck fistula, however, does make hepatic transplantation much more technically difficult, and therefore this procedure should be avoided in the transplant candidate. In addition to saving the patient’s life, hepatic transplantation reverses most of the hemodynamic and humoral changes associated with cirrhosis.

Budd-Chiari Syndrome
Budd-Chiari syndrome (BCS) is an uncommon congestive hepatopathy characterized by the obstruction of hepatic venous outflow. The incidence of BCS is 1 in 100,000 of the general population worldwide. Patients may present with acute signs and symptoms of abdominal pain, ascites, and hepatomegaly or more chronic symptoms related to long-standing portal hypertension. BCS is defined as primary when the obstructive process involves an endoluminal venous thrombosis. BCS is considered as a secondary process when the veins are compressed or invaded by a neighboring lesion originating outside the vein.

A thorough evaluation demonstrates one or more thrombotic risk factors in approximately 75% to 90% of patients with primary BCS. Primary myeloproliferative disorders, such as essential thrombocythemia or polycythemia rubra, account for approximately 35% to 50% of the primary cases of BCS. All known inherited thrombophilias also have been implicated in the development of BCS. Activated protein C resistance, generally related to factor V Leiden mutation, is present in approximately 25% of patients. Anticardiolipin antibodies, hyperhomocysteinemia, and oral contraceptive use all have been shown to be risk factors for BCS.

Clinically significant BCS is usually the result of obstruction of two or more of the major hepatic veins. The obstruction results in hepatomegaly, liver congestion, and right upper quadrant pain. In addition, liver perfusion via the portal vein may be decreased, and 70% of affected patients have noninflammatory centrilobular necrosis on biopsy. Although ALF is rare, most patients will go on to develop chronic portal hypertension and ascites. Caudate lobe hypertrophy occurs in approximately 50% of cases and is due to the fact that the caudate lobe has direct venous drainage into the IVC. This caudate lobe hypertrophy, in turn, can result in further obstruction of the IVC.
Abdominal ultrasonography is the initial investigation of choice and can demonstrate the absence of hepatic vein flow, spider web hepatic veins, and collateral hepatic veins. CT or MRI of the abdomen also is capable of demonstrating hepatic vein thrombosis and evaluating the IVC but is limited in that it cannot show direction of blood flow. The definitive radiographic study to evaluate BCS is hepatic venography to determine the presence and extent of hepatic vein thrombus as well as measure IVC pressures.

Initial treatment consists of diagnosing and medically managing the underlying disease process and preventing extension of the hepatic vein thrombosis through systemic anticoagulation. The BCS-associated portal hypertension and ascites can be medically managed in a manner similar to that in most cirrhotic patients. Radiologic and surgical intervention should be reserved for patients whose condition is nonresponsive to medical therapy. Percutaneous angioplasty and TIPS, in combination with thrombolytic therapy, are the preferred strategies to restore the outflow of blood from the liver. Thrombolytic therapy alone may be attempted for acute thrombosis. Surgical shunting, namely with the side-to-side portacaval shunt, essentially turns the portal vein into a hepatic outflow tract. Most patients with a portacaval shunt show improvement in hepatic function and the portal vein into a hepatic outflow tract. Thrombolytic therapy alone with thrombolytic therapy, are the preferred strategies to restore the outflow of blood from the liver. Thrombolytic therapy alone may be attempted for acute thrombosis. Surgical shunting, namely with the side-to-side portacaval shunt, essentially turns the portal vein into a hepatic outflow tract. Most patients with a portacaval shunt show improvement in hepatic function and fibrosis at 1 year without significant hepatic encephalopathy. However, the enthusiasm for this procedure has been curbed due to the relatively high rate of operative mortality and shunt dysfunction. Patients with progressive BCS and manifestations of ESLD will ultimately require hepatic transplantation.

**INFECTIONS OF THE LIVER**

The liver contains the largest portion of the reticuloendothelial system in the human body and is therefore able to handle the continuous low-level exposure to enteric bacteria that it receives through the portal venous system. Due to the high level of reticuloendothelial cells in the liver, nonviral infections are unusual.

**Pyogenic Liver Abscesses**

Pyogenic liver abscesses are the most common liver abscesses seen in the United States. They may be single or multiple and are more frequently found in the right lobe of the liver. The abscess cavities are variable in size and, when multiple, may coalesce to give a honeycomb appearance. Approximately 40% of abscesses are monomicrobial, an additional 40% are polymicrobial, and 20% are culture-negative. The most common infecting agents are gram-negative bacteria; *Escherichia coli* is found in two thirds of cases, and other common organisms include *Streptococcus faecalis*, *Klebsiella*, and *Proteus vulgaris*. Anaerobic organisms such as *Bacteroides fragilis* also are seen frequently. In patients with endocarditis and infected indwelling catheters, *Staphylococcus* and *Streptococcus* species are more commonly found.

In the past, pyogenic liver abscesses often resulted from infections of the intestinal tract such as acute appendicitis and diverticulitis, which then spread to the liver via the portal circulation. With improved imaging modalities and earlier diagnosis of these intra-abdominal infections, this particular etiology of pyogenic liver abscesses has become less common. Pyogenic liver abscesses also occur as a result of impaired biliary drainage, subacute bacterial endocarditis, infected indwelling catheters, dental work, or the direct extension of infections such as diverticulitis or Crohn’s disease into the liver. There appears to be an increasing incidence due to infection by opportunistic organisms among immunosuppressed patients, including transplant and chemotherapy recipients as well as patients with acquired immunodeficiency syndrome (AIDS).

Patients commonly present with right upper quadrant pain and fever. Jaundice occurs in up to one third of affected patients. A thorough history and physical examination are usually helpful in identifying the underlying cause of the liver abscess. Leukocytosis, an elevated sedimentation rate, and an elevated AP level are the most common laboratory findings. Significant abnormalities in the results of the remaining liver function tests are unusual. Blood cultures will only reveal the causative organism in approximately 50% of cases. Ultrasound examination of the liver reveals pyogenic abscesses as round or oval hypoechoic lesions with well-defined borders and a variable number of internal echoes. CT scan is highly sensitive in the localization of pyogenic liver abscesses, which appear hypodense with peripheral enhancement and may contain air-fluid levels indicating a gas-producing infectious organism (Fig. 31-16). MRI of the abdomen can also detect pyogenic abscesses with a high level of sensitivity but plays a limited role because of its inability to be used for image-guided diagnosis and therapy.

The current cornerstones of treatment include correction of the underlying cause and IV antibiotic therapy. Empiric antibiotic therapy should cover gram-negative and anaerobic organisms; percutaneous needle aspiration and culture of the aspirate may be useful in guiding subsequent antibiotic therapy. IV antibiotic therapy should be continued for at least 8 weeks and can be expected to be effective in 80% to 90% of patients. Placement of a percutaneous drainage catheter is beneficial only for a minority of patients, as most pyogenic abscesses are quite viscous and catheter drainage is often ineffective.

Surgical drainage either via the laparoscopic or open approach may become necessary if initial therapies fail. Anatomic surgical resection can be performed in patients with recalcitrant abscesses. It must be kept in mind throughout the evaluation and treatment of the presumed pyogenic abscess that a necrotic hepatic malignancy must not be mistaken for a hepatic abscess. Therefore, early diagnosis and progression to

*Figure 31-16. Computed tomographic scan of pyogenic liver abscesses. Multiple hepatic abscesses are seen in a patient after an episode of diverticulitis. Note the loculated large central abscess as well as the left lateral segment abscess.*
Amebic abscesses

*Entamoeba histolytica* is a parasite that is endemic worldwide, infecting approximately 10% of the world’s population. Amebiasis is most common in subtropical climates, especially in areas with poor sanitation. *E. histolytica* exists as cysts in a vegetative form that are capable of surviving outside the human body. The cystic form passes through the stomach and small bowel unharmed and then transforms into a trophozoite in the colon. Here it invades the colonic mucosa forming typical flask-shaped ulcers, enters the portal venous system, and is carried to the liver. Occasionally, the trophozoite will pass through the hepatic portal vein, enter the pulmonary capillary bed or enter the systemic circulation, which results in lung and brain abscesses.

Amebae multiply and block small intrahepatic portal radicles with consequent focal infarction of hepatocytes. They contain a proteolytic enzyme that also destroys liver parenchyma. The abscesses formed are variable in size and can be single or multiple. The amebic abscess is most commonly located in the superior-anterior aspect of the right lobe of the liver near the diaphragm and has a necrotic central portion that contains a thick, reddish brown, pus-like material. This material has been likened to anchovy paste or chocolate sauce. Amebic abscesses are the most common type of liver abscesses worldwide.

Amebiasis should be considered in patients who have traveled to an endemic area and present with right upper quadrant pain, fever, hepatomegaly, and hepatic abscess. Leukocytosis is common, whereas elevated transaminase levels and jaundice are unusual. The most common biochemical abnormality is a mildly elevated AP level. Even though this disease process is secondary to a colonic infection, the presence of diarrhea is unusual. Most patients have a positive fluorescent antibody test for *E. histolytica*, and test results can remain positive for some time after a clinical cure. This serologic test has a high sensitivity, and therefore amebiasis is unlikely if the test results are negative.

Ultrasound and CT scanning of the abdomen are both very sensitive but nonspecific for the detection of amebic abscesses. Amebic abscesses usually appear on CT as well-defined low-density round lesions that have enhancement of the wall, somewhat ragged in appearance with a peripheral zone of edema. The central cavity may have septations as well as fluid levels. CT scanning is also useful in the detection of extrahepatic involvement.

Metronidazole 750 mg three times a day for 7 to 10 days is the treatment of choice and is successful in 95% of cases. Defervescence usually occurs in 3 to 5 days, but the time necessary for the abscess to resolve depends on the initial size at presentation and varies from 30 to 300 days. Both ultrasound and CT of the liver can be used as follow-up after the initiation of medical therapy. Aspiration of the abscess rarely is needed and should be reserved for patients with large abscesses, those who do not respond to medical therapy, or those who appear to be superinfected. Furthermore, abscesses of the left lobe of the liver at risk for rupture into the pericardium should be treated with aspiration and drainage.

Hydatid disease is due to infection by the tapeworm *Echinococcus granulosus* in its larval or cyst stage. The tapeworm lives in canids, which are infected by eating the viscera of sheep that contain hydatid cysts. Scolices, contained in the cysts, adhere to the small intestine of dogs and become adult taenia, which attach to the intestinal wall. Each worm sheds approximately 500 ova into the bowel. The infected ova-containing feces of dogs contaminate grass and farmland, and the ova are ingested by intermediate hosts such as sheep, cattle, pigs, and humans. The ova have chitinous envelopes that are dissolved by gastric juice. The liberated ovum then burrows through the intestinal mucosa and is carried by the portal vein to the liver, where it develops into an adult cyst. Most cysts are caught in the hepatic sinusoids, and therefore 70% of hydatid cysts form in the liver. A few ova pass through the liver and are held up in the pulmonary capillary bed or enter the systemic circulation, forming cysts in the lung, spleen, brain, or bones.

Hydatid disease is most common in sheep-raising areas, where dogs have access to infected offal. These include South Australia, New Zealand, Africa, Greece, Spain, and the Middle East. Hydatid cysts commonly involve the right lobe of the liver, usually the anterior-inferior or posterior-inferior segments. The uncomplicated cyst may be silent and found only incidentally or at autopsy. Occasionally, the affected patient presents with symptoms such as dull right upper quadrant pain or abdominal distention. Cysts may become secondarily infected, involve other organs, or even rupture, which leads to an allergic or anaphylactic reaction.

The diagnosis of hydatid disease is based on the findings of an enzyme-linked immunosorbent assay (ELISA) for echinococcal antigens, and results are positive in approximately 85% of infected patients. The ELISA results may be negative in an infected patient if the cyst has not leaked or does not contain scolices or if the parasite is no longer viable. Eosinophilia is seen in approximately 30% of infected patients. Ultrasonography and CT scanning of the abdomen are both quite sensitive for detecting hydatid cysts. The appearance of the cysts on images depends on the stage of cyst development. Typically, hydatid cysts are well-defined hypodense lesions with a distinct wall. Ring-like calcifications of the pericyst are present in 20% to 30% of cases. As healing occurs, the entire cyst calcifies densely, and a lesion with this appearance is usually dead or inactive. Daughter cysts generally occur in a peripheral location within the main cyst and are typically slightly hypodense compared with the mother cyst. MRI of the abdomen may be useful to evaluate the pericyst, cyst matrix, and daughter cyst characteristics.

Unless the cysts are small or the patient is not a suitable candidate for surgical resection, the treatment of hydatid disease is surgically based because of the high risk of secondary infection and rupture. Medical treatment with albendazole relies on drug diffusion through the cyst membrane. The concentration of drug achieved in the cyst is uncertain but is better than that of mebendazole, and albendazole can be used as initial treatment for small, asymptomatic cysts. For most cysts, surgical resection involving laparoscopic or open complete cyst removal with instillation of a scolicidal agent is preferred and usually is curative. If complete cystectomy is not possible, then formal anatomic liver resection may be undertaken. During surgical resection, caution must be exercised to avoid rupture of the cyst with release of protoscolices into the peritoneal cavity. Peritoneal contamination can result in an acute anaphylactic reaction or peritoneal implantation of scolices with daughter cyst formation and inevitable recurrence.
Echinococcus multilocularis occurs in the Northern Hemisphere and can infect the liver in a fashion similar to that described earlier, although the cysts are multilocular. Infection of the lung also is common (alveolar echinococcosis). Canine species such as wolves, foxes, and dogs ingest infected viscera of an intermediate host (e.g., rodents, moose) and become infected; humans become infected incidentally by ingesting contaminated food or water. Treatment consists of albendazole; however, infection in the lung produces a more generalized granulomatous reaction, can present in a manner similar to that of a malignancy, and often requires resection.

Ascariasis

Ascaris infection is particularly common in the Far East, India, and South Africa. Ova of the roundworm Ascaris lumbricoides arrive in the liver by retrograde locomotion in the bile ducts from the GI tract. The adult worm is 10 to 20 cm long and may lodge in the common bile duct, causing partial bile duct obstruction and secondary cholangitic abscesses. The Ascaris may serve as a nidus for the development of intrahepatic gallstones. The clinical presentation in an affected patient may include biliary colic, acute cholecystitis, acute pancreatitis, or hepatic abscesses.48 Plain abdominal radiographs, abdominal ultrasound, and ERCP can demonstrate the Ascaris as linear filling defects within the bile ducts. Occasionally, worms can be seen moving into and out of the biliary tree from the duodenum. Treatment consists of the administration of piperazine citrate, mebendazole, or albendazole in combination with endoscopic extraction of the worms. Surgical intervention may become necessary if the Ascaris cannot be removed via ERCP.

Schistosomiasis

Schistosomiasis affects >200 million people in 74 countries. Hepatic schistosomiasis occurs when emboli of the ova in the intestines reach the liver via the mesenteric venous system. Eggs excreted in the feces hatch in water to release free-swimming embryos, which enter snails and develop into fork-tailed cercariae. They then re-enter human skin during contact with infected water. They burrow down to the capillary bed and enter the bloodstream, leading to widespread hematogenous dissemination. Those entering the intrahepatic portal system grow rapidly, resulting in a granulomatous reaction. The degree of consequent portal fibrosis is related to the adult worm load.

Schistosomiasis has three stages of clinical symptomatology: the first includes itching after the entry of cercariae through the skin; the second includes fever, urticaria, and eosinophilia; and the third involves hepatic fibrosis followed by presinusoidal portal hypertension. During this third phase, the liver shrinks, the spleen enlarges, and the patient may develop complications of portal hypertension while hepatic function is maintained. Active infection is detected by stool examination. Serologic tests indicate past exposure but do not provide information regarding the timing of infection. A negative serologic test result excludes the presence of schistosomal infection. Serum levels of transaminases are usually normal, but the AP level may be mildly elevated. A decreased serum albumin level is usually the result of frequent GI bleeds and malnutrition.

Medical treatment of schistosomiasis includes education on hygiene and the avoidance of infected water. Treatment with praziquantel 40 to 75 mg/kg as a single dose is the treatment of choice for all forms of schistosomiasis and produces few side effects. GI bleeding usually is controlled by endoscopic variceal ligation. However, in a patient with refractory GI portal hypertensive bleeding, distal splenorenal shunt or gastric devascularization and splenectomy may be considered.

Viral Hepatitis

The role of the surgeon in the management of viral hepatitis is somewhat limited. However, the disease entities of hepatitis A, B, and C need to be kept in mind during any evaluation for liver disease. Hepatitis A usually results in an acute self-limited illness and only rarely leads to fulminant hepatic failure. Patients can present with fatigue, malaise, nausea, vomiting, anorexia, fever, and right upper quadrant abdominal pain. The most common physical findings are jaundice and hepatomegaly. Because the disease is self-limited, the treatment is usually supportive. Patients who develop fulminant infection require aggressive therapy and should be transferred to a center capable of performing liver transplantation.

Hepatitis B and C, on the other hand, can both lead to chronic liver disease, cirrhosis, and HCC. The prevalence of chronic hepatitis B infection in the U.S. population is estimated to be 0.27%, but hepatitis B remains a major burden in resource-limited countries, accounting for 30% of cirrhosis and 53% of HCC cases. The ultimate goal of treatment for chronic hepatitis B is viral suppression, thereby preventing the development of clinical outcomes such as cirrhosis, liver failure, and HCC. The cornerstone of current antiviral therapy includes pegylated interferon and nucleoside analogs such as tenofovir or entecavir.49 These agents have been proven to reduce complications of cirrhosis and HCC and perhaps reverse previous damage to the liver. Interferon therapy produces various side effects including fatigue, flu-like symptoms, mood changes, bone marrow suppression, and stimulation of autoimmunity. On the other hand, the nucleoside analogs are generally well-tolerated by patients. Compared with lamivudine, the nucleoside analogs are less likely to produce resistance and are more likely to be clinically effective. Despite its high rate of viral resistance, lamivudine may be the preferred treatment in some countries because of its relatively low cost.

Acute hepatitis C viral (HCV) infection typically develops 2 to 26 weeks after exposure to the virus, and presenting symptoms can include jaundice, nausea, dark urine, and right upper quadrant abdominal pain. Diagnosis is confirmed by testing for the presence of HCV RNA and anti-HCV antibodies in the serum; viral RNA is first detectable in the serum by polymerase chain reaction (PCR) within days to weeks following exposure, whereas antibodies will not appear until 2 to 6 months after. If the diagnosis of acute hepatitis is established and the virus is not spontaneously cleared within 12 weeks, patients should generally be treated with pegylated interferon monotherapy. High rates of sustained viral response, in excess of 80%, have been achieved with the early treatment of acute HCV infection.50 Unfortunately patients with acute HCV infection are typically asymptomatic, and the vast majority of cases go undetected. Untreated, most of these patients will eventually develop chronic infection.

Chronic HCV infection often follows a progressive course over many years and can ultimately result in cirrhosis, HCC, and the need for liver transplantation. Cirrhosis secondary to hepatitis C remains the leading indication for liver transplantation in the United States, Europe, and Japan. The decision to treat a patient with chronic HCV infection is complex and involves consideration of multiple factors including the natural history of...
the disease, stage of fibrosis, and the efficacy and adverse effects related to the treatment regimen. Patients with genotype 1 are now treated with triple-agent therapy including pegylated interferon, ribavirin, and a protease inhibitor. The protease inhibitors telaprevir and boceprevir were recently approved for the treatment of chronic HCV genotype 1 infection, and their addition to the treatment regimen has been shown to increase the rate of sustained viral response from 40% to 70%. These protease inhibitors do not exhibit significant antiviral activity against other HCV genotypes, and therefore genotypes 2, 3, and 4 are treated with interferon and ribavirin alone. Genotypes 2 and 3 are generally more responsive to treatment than genotypes 1 and 4, but the therapeutic response also depends on other factors such as baseline viral load, ethnicity, and the patient’s genetic background and compliance with the regimen.

**EVALUATION OF AN INCIDENTAL LIVER MASS**

A liver mass often is identified incidentally during a radiologic imaging procedure performed for another indication. For example, a liver mass may be discovered during evaluation for gallbladder disease or kidney stones. In addition, with advances in imaging technology, previously undetected lesions not infrequently are now identified. Although many of these lesions are benign and will require no further treatment, the concern for malignancy requires a thorough evaluation. Thus, an orderly approach should be taken to the workup of an incidental liver lesion to minimize unnecessary testing.

The evaluation of an incidental liver mass begins with a history and physical examination (Fig. 31-17). The patient should be asked about abdominal pain, weight loss, previous liver disease, cirrhosis, alcohol use, viral hepatitis, blood transfusions, tattoos, oral contraceptive use (in women), and personal or family history of cancer. On physical examination, jaundice, scleral icterus, hepatomegaly, splenomegaly, palpable mass, or stigmata of portal hypertension should be noted. After completion of the history and physical examination, blood work should be performed, including complete blood count; platelet count; measurement of levels of electrolytes, blood urea nitrogen, creatinine, glucose, and albumin; liver function tests; serum ammonia level; coagulation studies; hepatitis screen; and measurement of levels of the

HEPATIC CYSTS

**Congenital Cysts**

The majority of hepatic cysts are asymptomatic. Hepatic cysts are usually identified incidentally and can occur at any time throughout life. The most common benign lesion found in the liver is the congenital or simple cyst. The exact prevalence of simple hepatic cysts in the U.S. population is not known, but the female:Male ratio is approximately 4:1, and the prevalence is approximately 2.8% to 3.6%. Simple cysts are the result of excluded hyperplastic bile duct rests. Simple cysts usually are identified in hepatic imaging studies as thin-walled, homogeneous, fluid-filled structures with few to no septations. The cyst epithelium is cuboidal and secretes a clear nonbilius serous fluid. With the exception of large cysts, simple cysts are usually asymptomatic. Large simple cysts may cause abdominal pain, epigastric fullness, and early satiety. Occasionally, the affected patient presents with an abdominal mass.

Asymptomatic simple cysts are best managed conservatively. The preferred treatment for symptomatic cysts is ultrasonography-guided aspiration of cyst fluid. This approach is approximately 90% effective in controlling symptoms and abating the cyst cavity. If percutaneous treatment is unavailable or ineffective, treatment may include either laparoscopic or open surgical cyst fenestration. The laparoscopic approach is being used more frequently and is 90% effective. The excised cyst wall is sent for pathologic analysis to exclude the presence of carcinoma, and the remaining cyst wall must be carefully inspected for evidence of neoplastic change. If such change is present, complete resection is required, either by enucleation or formal hepatic resection.

**Biliary Cystadenoma**

Biliary cystadenomas are slow-growing, unusual, benign lesions that most commonly present as large lesions in the right lobe of the liver. Although these lesions are usually benign, they can undergo malignant transformation. Patients with biliary cystadenomas commonly present with abdominal pain. An abdominal mass occasionally can be identified on physical examination. In contrast to simple cysts, biliary cystadenomas have walls that appear thicker with soft tissue nodules and septations that usually enhance. The protein content of the fluid can be variable and can affect the radiographic images on CT and MRI. Surgical resection is the preferred mode of treatment.

**Polycystic Liver Disease**

Adult polycystic liver disease (PCLD) occurs as an autosomal dominant disease and usually presents in the third decade of life. Approximately 44% to 76% of affected families are found to have mutations of PKD1, and approximately 75% have mutations of PKD2. The prevalence and number of hepatic cysts are higher in females and increase with advancing age and with increasing severity of renal cystic disease and renal dysfunction. Patients with a small number of cysts or with small cysts (<2 cm) usually remain asymptomatic. In contrast, patients who develop many or large cysts, with a cyst-to-parenchymal volume ratio of >1, usually develop clinical symptoms, including abdominal pain, distension, shortness of breath, and early satiety. Disease progression often results in renal failure and the need for hemodialysis. In most patients, the liver parenchymal volume and synthetic function are preserved despite extensive cystic disease. Hepatic decompensation, variceal hemorrhage, ascites,

The differential diagnosis for an incidental liver mass includes cysts, benign solid lesions, and primary or metastatic cancers (Table 31-6). Ultrasound or CT is commonly performed to evaluate respiratory or abdominal symptoms, and these imaging studies usually lead to the discovery of an incidental liver lesion. Further radiologic evaluation by dual- or triple-phase CT scan or MRI is often necessary to fully characterize the extent and nature of the lesion. Different types of liver masses have distinct appearances and patterns of contrast enhancement on these studies, facilitating the clinician in the diagnosis and formulation of the treatment plan. The use of liver-specific contrast agents in MRI provides information on hepatocyte function in combination with the structural data obtained during a standard MRI, and yields improved detection and characterization of liver lesions. CT cholangiography or MRCP can be obtained, particularly when visualization of the biliary tract is desired. These modalities may be useful in the depiction of benign or malignant strictures resulting in biliary obstruction. In the evaluation of metastases to the liver from a variety of primary cancers, FDG-PET/CT has emerged as an indispensable tool in disease staging and in the follow-up after treatment. The techniques available for imaging of liver lesions are described in detail earlier in the section “Radiologic Evaluation of the Liver.”

Laparoscopic liver biopsy is indicated when biochemical analysis and diagnostic imaging fail to lead to a definitive diagnosis. Percutaneous liver biopsy with ultrasound or CT guidance is the simplest, fastest, and most commonly performed approach to obtain hepatic tissue for histologic examination. Absolute contraindications to percutaneous liver biopsy include significant coagulopathy (as in patients with decompensated cirrhosis), biliary dilatation, and suspicion for hemangiomia or echinococcal cyst. Obesity and the presence of ascites are relative contraindications that can present a challenge to the percutaneous approach. In these patients, laparoscopic liver biopsy can be considered. The laparoscopic technique is likely to have a higher diagnostic yield in cirrhotic patients with ascites and/or coagulopathy, in whom bleeding risk is excessive by the percutaneous route. Laparoscopy also offers the opportunity to stage the extent of disease in patients with various intra-abdominal malignancies.
and encephalopathy develop rarely in patients with PCLD and only in those with massive cystic disease. The most common liver-specific complications associated with PCLD are intracystic hemorrhage, infection, and posttraumatic rupture. The most common abnormal biochemical test finding is a modestly elevated γ-glutamyltransferase level, and the most useful imaging tests are CT or MRI of the abdomen, which will demonstrate the characteristic polycystic appearance. Other conditions that may be associated with PCLD include cerebral aneurysm, diverticulosis, mitral valve prolapse, and inguinal hernia.

The principal aim of treatment for PCLD is to ameliorate symptoms by decreasing liver volume. Medical therapy options for PCLD remain experimental at this time. Somatostatin analogs such as octreotide and lanreotide have been shown to modestly reduce liver volume and are generally well tolerated. Sirolimus and other mammalian target of rapamycin (mTOR) inhibitors possess antiproliferative effects and thus have been postulated to slow disease progression. The effectiveness of these medical measures in relieving symptoms among patients with PCLD, however, remains to be proven.54

Cyst aspiration and sclerotherapy entail puncture of a cyst with an aspiration needle followed by injection of a sclerosing agent that causes destruction of the epithelial lining thereby inhibiting fluid production. Common agents used for sclerosis include ethanol, minocycline, and tetracycline. This technique may be considered if the patient has one or a few dominant cysts, each measuring over 5 cm. Appropriate candidates for sclerotherapy can experience a complete resolution of symptoms, but patients with numerous cysts often do not improve when this technique is used. This procedure is generally well tolerated, with the most common complication being pain from the instillation of ethanol.

Cyst fenestration, or surgical unroofing of the cyst, can be performed via an open or laparoscopic approach in symptomatic patients.55 This approach allows multiple cysts to be treated during a single procedure, but carries the risk of potential surgical complications, including ascites, pleural effusion, hemorrhage, and biliary leakage. Immediate symptom relief can be achieved in up to 92% of cases, but 22% of patients eventually develop recurrence of their symptoms. Hepatic resection can be considered for PCLD patients with massive hepatomegaly, when fenestration alone is unlikely to significantly reduce liver volume. Appropriate candidates are those with portions of liver that harbor numerous cysts, but have at least one spared segment with predominantly normal liver parenchyma. Because the intrahepatic vascular and biliary anatomy can be distorted by the cysts, PCLD patients undergoing hepatic resection are at increased risk for hemorrhagic and biliary complications. Furthermore, adhesion formation after liver resection can increase the technical complexity of future OLT. Significant symptom relief has been reported in up to 86% of PCLD patients following hepatic resection.

OLT represents the only definitive therapy for patients with symptomatic PCLD. This therapeutic option is indicated in patients with severely disabling symptoms that lead to a poor quality of life or in those who have developed untreatable complications such as portal hypertension and nutritional deprivation. If the patient has severe renal insufficiency from polycystic kidney disease, consideration should be given to combined liver-kidney transplantation. Because of the genetic basis of PCLD, living-donor transplantation should be considered only if the presence of PCLD in the donor can be ruled out.

**Carolí’s Disease**

Carolí’s disease is a syndrome of congenital ductal plate malformations of the intrahepatic bile ducts and is characterized by segmental cystic dilatation of the intrahepatic biliary radicals.56 Carolí’s disease also is associated with an increased incidence of biliary lithiasis, cholangitis, and biliary abscess formation. Carolí’s disease usually occurs in the absence of cirrhosis and is associated with cystic renal disease.56 The most common presenting symptoms include fever, chills, and abdominal pain. Most patients present by the age of 30 years, and males and females are affected equally. Rarely, patients can present later in life with complications secondary to portal hypertension. Approximately 33% of affected patients develop biliary lithiasis and 7% develop cholangiocarcinoma. The diagnosis of Carolí’s disease is made based on imaging studies. Magnetic resonance cholangiopancreatography, ERCP, and percutaneous transhepatic cholangiography provide more detailed imaging of the biliary tree and confirm communication of the intrahepatic cysts with the biliary tree, which is necessary to solidify the diagnosis. Treatment consists of biliary drainage, with ERCP and percutaneous transhepatic cholangiography serving as first-line therapeutic modalities. If the disease is limited to a single lobe of the liver, hepatic resection can be beneficial. Liver resection can be considered in the patient with hepatic decompensation or unresponsive recurrent cholangitis and possibly in the patient with a small (T1 or T2) cholangiocarcinoma.

**Benign Liver Lesions**

The liver is an organ that is commonly involved either primarily or secondarily with vascular, metabolic, infectious, and malignant processes. Many classification schemes are used to help narrow the differential diagnosis of liver lesions: solid or cystic, single or multiple, cell of origin (hepatocellular, cholangiocellular, or mesenchymal), and benign or malignant. Benign liver lesions occur in up to 20% of the general population and are much more common than malignant tumors. The most common benign lesions are cysts, hemangiomas, focal nodular hyperplasia (FNH), and hepatocellular adenomas (see Table 31-6). Many of these lesions have typical features in imaging studies that help confirm the diagnosis.

**Cyst**

Hepatic cysts are the most frequently encountered liver lesion overall and are described in detail in the section “Hepatic Cysts.” Cystic lesions of the liver can arise primarily (congenital) or secondarily from trauma (seroma or biloma), infection (pyogenic or parasitic), or neoplastic disease. Congenital cysts are usually simple cysts containing thin serous fluid and are reported to occur in 5% to 14% of the population, with higher prevalence in women. In most cases, congenital cysts are differentiated from secondary cysts (infectious or neoplastic origin) in that they have a well-defined thin wall and no solid component and are filled with homogeneous, clear fluid. For benign solid liver lesions, the differential diagnosis includes hemangioma, adenoma, FNH, and bile duct hamartoma.

**Hemangioma**

Hemangiomas (also referred to as hemangiomata) are the most common solid benign masses that occur in the liver. They consist of large endothelial-lined vascular spaces and represent
congenital vascular lesions that contain fibrous tissue and small blood vessels that eventually grow. They are predominantly seen in women and occur in 2% to 20% of the population. They can range from small (≤1 cm) to giant cavernous hemangiomas (10 to 25 cm). Most hemangiomas are discovered incidentally with little clinical consequence. However, large lesions can cause symptoms as a result of compression of adjacent organs or intermittent thrombosis, which in turn results in further expansion of the lesion. Spontaneous rupture (bleeding) is rare, but surgical resection can be considered if the patient is symptomatic. Resection can be accomplished by enucleation or formal hepatic resection, depending on the location and involvement of intrahepatic vascular structures and hepatic ducts.

The majority of hemangiomas can be diagnosed by liver imaging studies. On biphasic contrast CT scan, large hemangiomas show asymmetrical nodular peripheral enhancement that is isodense with large vessels and exhibit progressive centripetal enhancement fill-in over time (Fig. 31-18). On MRI, hemangiomas are hypointense on T1-weighted images and hyperintense on T2-weighted images. With gadolinium enhancement, hemangiomas show a pattern of peripheral nodular enhancement similar to that seen on contrast CT scans. Cautions should be exercised in ordering a liver biopsy if the suspected diagnosis is hemangioma because of the risk of bleeding from the biopsy site, especially if the lesion is at the edge of the liver.

**Adenoma**

Hepatic adenomas are benign solid neoplasms of the liver. They are most commonly seen in premenopausal women older than 30 years of age and are typically solitary, although multiple adenomas also can occur. Prior or current use of estrogens (oral contraceptives) is a clear risk factor for development of liver adenomas, although they can occur even in the absence of oral contraceptive use. On gross examination, they appear soft and encapsulated and are tan to light brown. Histologically, adenomas lack bile duct glands and Kupffer cells, have no true lobules, and contain hepatocytes that appear congested or vacuolated due to glycogen deposition. On CT scan, adenomas usually have sharply defined borders and can be confused with metastatic tumors. With venous phase contrast, they can look hypodense or isodense in comparison with background liver, whereas on arterial phase contrast, subtle hypervascular enhancement is often seen (see Fig. 31-18). On MRI scans, adenomas are hyperintense on T1-weighted images and enhance early after gadolinium injection. With the use of liver-specific MRI contrast agents such as gadoxetate (Eovist or Primovist, Bayer-Schering, Berlin, Germany), hepatic adenomas can be

---

Figure 31-18. Computed tomographic scans showing classic appearance of benign liver lesions. Focal nodular hyperplasia (FNH) is hypervascular on arterial phase, isodense to liver on venous phase, and has a central scar (upper panels). Adenoma is hypovascular (lower left panel). Hemangioma shows asymmetrical peripheral enhancement (lower right panel).
better distinguished from FNH by their enhancement characteristics during the hepatobiliary phase of imaging. The new MRI contrast agent, gadobenate dimeglumine (MultiHance, Bracco Diagnostics, Milan, Italy), is eliminated through both renal and biliary excretion. Therefore, liver lesions that contain hepatocytes with intact biliary excretion mechanism will take up this contrast agent and be easily distinguished from lesions that do not. This contrast agent has improved our ability to differentiate hepatic adenoma from FNH with a high degree of accuracy. Hepatic adenomas carry a significant risk of spontaneous rupture with intraperitoneal bleeding. The clinical presentation may be abdominal pain, and in 10% to 25% of cases, hepatic adenomas present with spontaneous intraperitoneal hemorrhage. Hepatic adenomas also have a risk of malignant transformation to a well-differentiated HCC. Therefore, it usually is recommended that a hepatic adenoma (once diagnosed) be surgically resected.

Focal Nodular Hyperplasia
FNH is a solid, benign lesion of the liver believed to be a hyperplastic response to an anomalous artery. Similar to adenomas, they are more common in women of childbearing age, although the link to oral contraceptive use is not as clear as with adenomas. A good-quality biphasic CT scan usually is diagnostic of FNH, on which such lesions appear well circumscribed with a typical central scar (see Fig. 31-18). They show intense homogeneous enhancement on arterial phase contrast images and are often isodense or invisible compared with background liver on the venous phase. On MRI scans, FNH lesions are hypointense on T1-weighted images and isointense to hyperintense on T2-weighted images. After gadolinium administration, lesions are hyperintense but become isointense on delayed images. The fibrous septa extending from the central scar are also more readily seen with MRI. Unlike adenomas, FNH lesions usually do not rupture spontaneously and have no significant risk of malignant transformation. Therefore, the management of FNH is usually reassurance and prospective observation irrespective of size. Surgical resection can be recommended, however, when patients are symptomatic or when hepatic adenoma or HCC cannot be definitively excluded. Oral contraceptive or estrogen use should be stopped when either FNH or adenoma is diagnosed.

Bile Duct Hamartoma
Bile duct hamartomas are typically small liver lesions, 2 to 4 mm in size, visualized on the surface of the liver at laparotomy. They are firm, smooth, and whitish yellow in appearance. They can be difficult to differentiate from small metastatic lesions, and excisional biopsy often is required to establish the diagnosis.

MALIGNANT LIVER TUMORS
Malignant tumors in the liver can be classified as primary (cancers that originate in the liver) or metastatic (cancers that spread to the liver from an extrapathic primary site) (see Table 31-6). Primary cancers in the liver that originate from hepatocytes are known as hepatocellular carcinomas (HCCs) or hepato- mas), whereas cancers arising in the bile ducts are known as cholangiocarcinomas. In the United States, approximately 150,000 new cases of colorectal cancer are diagnosed each year, and the majority of patients (approximately 60%) will develop hepatic metastases over their lifetime. Hence, the most common tumor seen in the liver is metastatic colorectal cancer. This compares with approximately 18,000 new cases of HCC diagnosed annually in the United States. Interestingly, in a Western series of 1000 consecutive new liver cancer patients seen at a university medical center, 47% had HCC, 17% had colorectal cancer metastases, 11% had cholangiocarcinomas, 7% had neuroendocrine metastases, and 18% had other tumors. Although these figures do not reflect the incidence or prevalence of these liver cancers, they are indicative of referral patterns in a tertiary academic medical center with a large liver transplantation team and active hepatology clinic.

Hepatocellular Carcinoma
HCC is the fifth most common malignancy worldwide, with an estimated 750,000 new cases diagnosed annually. Because of its high fatality, it is the third most common cause of cancer death worldwide. Major risk factors are viral hepatitis (B or C), alcoholic cirrhosis, hemochromatosis, and NASH. In Asia, the risk is as high as 35 to 117 per 100,000 persons per year, whereas in the United States, the risk is only 7 per 100,000 persons per year. Although cirrhosis is not present in all cases, it has been estimated to be present 70% to 90% of the time. In a person with cirrhosis, the annual conversion rate to HCC is 2% to 6%. In patients with chronic HCV infection, cirrhosis usually is present before the HCC develops; however, in cases of hepatitis B virus infection, HCC tumors can occur before the onset of cirrhosis. HCCs are typically hypervascular with blood supplied predominantly from the hepatic artery. Thus, the lesion often appears hypervascular during the arterial phase of CT studies (Fig. 31-19) and relatively hypodense during the delayed phases due to early washout of the contrast medium by the arterial blood. MRI imaging also is effective in characterizing HCC. HCC is variable on T1-weighted images and usually hyperintense on T2-weighted images. As with contrast CT, HCC enhances in the arterial phase after gadolinium injection because of its hypervascularity and becomes hypointense in the delayed phases due to contrast washout. HCC has a tendency to invade the portal vein, and the presence of an enhancing portal vein thrombus is highly suggestive of HCC.

The treatment of HCC is complex and is best managed by a multidisciplinary liver transplant team. A complete algorithm for the evaluation and management of HCC is shown (Fig. 31-20). For patients without cirrhosis who develop HCC, resection is the treatment of choice. For patients with Child’s class A cirrhosis with preserved liver function and no portal hypertension, resection also is considered. If resection is not possible because of poor liver function and the HCC meets transplant criteria (discussed later), liver transplantation is the treatment of choice.6,12 The Barcelona-Clinic Liver Cancer Group has refined its HCC management strategy and has developed the American Association for the Study of Liver Diseases Practice Guidelines. Management guidelines vary slightly in Asia, Europe, the United States, and other countries based in part on availability of organ donors for liver transplantation. Living donor liver transplantation also is an alternative for patients with HCC awaiting transplantation to avoid dropout as a candidate for cadaveric donor liver transplantation due to tumor progression. Specific treatment options are described in the next section.

Cholangiocarcinoma
Cholangiocarcinoma, or bile duct cancer, is the second most common primary malignancy of the liver. Cholangiocarcinoma is an adenocarcinoma of the bile ducts; it forms in the biliary epithelial cells and can be subclassified into peripheral
Hilar cholangiocarcinoma is difficult to diagnose and typically presents as a stricture of the proximal hepatic duct causing painless jaundice. It preferentially grows along the length of the bile ducts, often involving the periductal lymphatics with frequent lymph node metastases. Surgical resection offers the only chance for cure of cholangiocarcinoma. The location and extent of tumor dictate the operative approach. In one series of 225 patients with hilar cholangiocarcinoma, 65 (29%) were deemed to have unresectable tumors by initial imaging. Of the remaining 160 patients who underwent exploratory surgery with curative intent, 80 (50%) were found to have inoperable tumors. Histologically negative margins, concomitant hepatic resection, and well-differentiated tumor histology were associated with improved outcome after resection. In another series of 61 patients undergoing surgical exploration for hilar cholangiocarcinoma, the 5-year actuarial survival rates for an R0 or R1 resection were 45% and 26%, respectively. In a large series reported by Nagino and colleagues, 132 patients with hilar cholangiocarcinoma underwent extended hepatectomy with resection of the caudate lobe and extrahepatic bile duct, and/or portal vein resection (n = 63) after portal vein embolization. The 3- and 5-year survival rates were 41.7% and 26.8%, respectively.

In the absence of associated primary sclerosing cholangitis (PSC), surgical resection is the treatment of choice for hilar cholangiocarcinoma. However, approximately 10% of patients with cholangiocarcinoma have PSC. Furthermore, cholangiocarcinoma in the setting of PSC is frequently multicentric and often is associated with underlying liver disease, with eventual cirrhosis and portal hypertension. As a result, experience has shown that resection of cholangiocarcinoma in patients with PSC yields dismal results. This led transplant centers to consider OLT for patients with hilar cholangiocarcinoma. The initial results of transplantation were disappointing, however, with high recurrence and overall 3-year survival rates of <30%.

Because the growth of hilar cholangiocarcinoma indicates that this disease spreads in a locoregional manner, a rationale for the use of neoadjuvant chemoradiation was developed by the transplant team at the University of Nebraska in the late 1980s. This was adapted in 1993 by the transplant team at the Mayo Clinic, which led to the current Mayo Clinic protocol. The pretransplant Mayo protocol consists of external-beam radiation therapy plus a protracted course of intravenous 5-fluorouracil followed by iridium-192 brachytherapy. Patients then undergo an abdominal exploration with staging. If findings are negative, patients are given capecitabine for 2 of every 3 weeks until transplantation. Even after restaging with CT/MRI and endoscopic ultrasonography, approximately 15% to 20% of patients will have positive findings for tumor on abdominal exploration. The 5-year survival rate for those undergoing transplantation for cholangiocarcinoma at the Mayo Clinic is approximately 70% and compares favorably with the rate for resection. Current eligibility criteria for this Mayo Clinic protocol include unresectable hilar cholangiocarcinoma or hilar cholangiocarcinoma with PSC. The tumor must have a radial dimension of ≤3 cm with no intrahepatic or extrahepatic metastases, and the patient must not have undergone prior radiation therapy or transperitoneal biopsy. Many centers have adopted similar protocols with comparable results.

Peripheral, or intrahepatic, cholangiocarcinoma is less common than hilar cholangiocarcinoma. In a series of 53 patients...
Gallbladder Cancer

Gallbladder cancer is a rare aggressive tumor with a very poor prognosis. Over 90% of patients have associated cholelithiasis. In one study examining the mode of presentation over a 10-year period from 1990 to 2000 in 44 patients diagnosed with gallbladder cancer, the diagnosis was found to be made preoperatively in 57%, intraoperatively in 11%, and incidentally after cholecystectomy in 32%. Surgical approaches can be classified into (a) reoperation for an incidental finding of gallbladder cancer after cholecystectomy, and (b) radical resection for metastatic colorectal cancer to the liver, if technically feasible, should be performed only for fewer than four metastases. However, later studies challenged this paradigm. In a series of 235 patients who underwent hepatic resection for metastatic colorectal cancer, the 10-year survival rate of patients with four or more nodules was 29%, nearly comparable to the 32% survival rate of patients with one to three nodules. In this respect, reoperation should be considered for all patients who have T2 or T3 tumors or for whom the accuracy of staging is in question.

Metastatic Colorectal Cancer

Over 50% to 60% of patients diagnosed with colorectal cancer will develop hepatic metastases during their lifetime. Resection for hepatic metastases has been a routine part of treatment for colorectal cancer since the publication of a large single-center experience demonstrating its safety and efficacy. Predictors of poor outcome in that study included node-positive primary, disease-free interval <12 months, more than one tumor, tumor size >5 cm, and carcinoembryonic antigen level >200 ng/mL. Traditional teaching suggested that hepatic resection for metastatic colorectal cancer to the liver, if technically feasible, should be performed only for fewer than four metastases. However, later studies challenged this paradigm. In a series of 235 patients who underwent hepatic resection for metastatic colorectal cancer, the 10-year survival rate of patients with four or more nodules was 29%, nearly comparable to the 32% survival rate of patients.
with only a solitary tumor metastasis. In the Memorial Sloan-Kettering Cancer Center series of 98 patients with four or more colorectal hepatic metastases who underwent resection between 1998 and 2002, the 5-year actuarial survival was 33%.[5] Furthermore, improved chemotherapeutic regimens and surgical techniques have produced aggressive strategies for the management of this disease. Many groups now consider volume of future liver remnant and the health of the background liver, and not actual tumor number, as the primary determinants in selection for an operative approach. [56,57] Hence, resectability is no longer defined by what is actually removed, but indications for hepatic resection now center on what will remain after resection. Use of neoadjuvant chemotherapy, portal vein embolization, two-stage hepatectomy, simultaneous ablation, and resection of extrahepatic tumor in select patients have increased the number of patients eligible for a surgical approach.[80,90]

Neuroendocrine Tumors
Hepatic metastases from neuroendocrine tumors have a protracted natural history and commonly are associated with debilitating endocrinopathies. Several groups have advocated an aggressive surgical approach of debulking surgery, both to control symptoms and to extend survival.[91,92] In a series of 170 patients undergoing resection of hepatic metastases from neuroendocrine tumors between 1977 and 1998 at the Mayo Clinic, overall survival was 61% and 35% at 5 and 10 years, respectively.[93] There was no difference in survival between patients with carcinoid tumors and those with islet cell tumors. Major hepatectomy was performed in 91 patients (54%), and recurrence rate was 84% at 5 years. Belghiti’s group has described a two-stage strategy used in 41 patients with a primary neuroendocrine tumor and synchronous bilobar liver metastases.[94] In the first stage, the primary tumor is resected and limited resection of metastases in the left hemiliver, combined with right portal vein ligation, is performed. After 8 weeks of hyperthermia, a right hepatectomy or extended right hepatectomy (also referred to as a right trisectionectomy: resection of Couinaud’s segments IV, V, VI, VII, and VIII of the liver) is performed.[95] In patients treated using this strategy, the 2-, 5-, and 8-year Kaplan-Meier overall survival rates were 94%, 94%, and 79%, respectively, and disease-free survival rates were 85%, 50%, and 26%, respectively. Because systemic therapy has had little success in the treatment of advanced tumors, a broader approach using multimodal therapy has been used to increase survival and improve hormone-related symptoms. These therapies include radiofrequency or microwave ablation and intra-arterial therapy with chemoembolization or radioembolization (yttrium-90). Some centers perform liver transplantation for selected patients (carcinoid histology; primary tumor removed with curative resection; primary tumor drained by portal system; ≤50% hepatic parenchyma involved; good response or stable disease for at least 6 months during pretransplantation period; and age 55 years or younger), although this is not routine.[96]

Other Metastatic Tumors
Nearly every cancer has the propensity to metastasize to the liver. Historically, enthusiasm was low for resecting metastases other than those from a colorectal cancer primary. This was due in part to the recognition that many other primary cancers (such as breast cancer) represent a systemic disease when liver metastases are present. However, more recent studies have shown acceptable 5-year survival rates in the 20% to 40% range for resection of hepatic metastases from breast, renal, and other GI tumors.[96,97] In a large study of hepatic resection for colorectal, nonendocrine liver metastases in 1452 patients, negative prognostic factors were nonbreast origin, age >60 years, disease-free interval of <12 months, need for major hepatectomy, performance of R2 resection, and presence of extrahepatic metastases.[96]

TREATMENT OPTIONS FOR LIVER CANCER
In general, the major treatment options for liver cancer can be categorized as shown in Table 31-7. The decision making for any given patient is complex and is best managed by a multidisciplinary liver tumor board. The treatments listed in Table 31-7 are not mutually exclusive; the important point is to select the most appropriate initial treatment after a complete evaluation. In general, surveillance imaging (CT or MRI) is performed every 3 to 4 months during the first year after diagnosis to observe for response, progression, or recurrence. The treatment plan is individualized and modified according to the response of the patient.

Hepatic Resection
For primary liver cancers or hepatic metastases, hepatic resection is the gold standard and treatment of choice. Although there are anecdotal reports of long-term survival after ablation and other regional liver therapies, liver resection remains the only real option for cure. For HCC in the setting of cirrhosis, liver transplantation also offers the potential for long-term survival, albeit with the consequences of immunosuppression. Hepatic resection also has been advocated for HCC in select patients with cirrhosis before secondary liver transplantation, although not without some controversy. Many large series of patients undergoing major hepatectomy now report mortality rates of <5%. Previously, a 1-cm tumor margin was considered desirable; however, recent studies have reported comparable survival rates with smaller margins.[103-105] Technical innovation in liver surgery and a better understanding of perioperative care have even allowed surgeons to perform resections in cases with IVC involvement.

Systemic chemotherapy
Multimodality approach
with extracorporeal liver surgery. The technical aspects of anatomic hepatic lobectomies are described later.

Liver Transplantation

The rationale supporting OLT for HCC includes the fact that most HCCs (>80%) arise in the setting of cirrhosis. The cirrhotic liver often does not have enough reserve to tolerate a formal resection. Also, HCC tumors are commonly multifocal and are underestimated by current CT or MRI imaging. Furthermore, recurrence rates are high at 5 years after resection (>50%). Hence, OLT is an appealing treatment, because it removes both the cancer and the cirrhotic liver that leads to cancer. More than 6000 liver transplantsations are performed each year in the United States, with 1-year survival rates approaching 90%. In June 2013, approximately 15,800 patients were on the waiting list for liver transplantation.

Initial series of OLT for HCC reported in the 1990s included advanced cases of HCC, and the 5-year survival rates were only 20% to 50%. This compared poorly with overall 5-year survival rates of 70% to 75% for OLT in the Organ Procurement and Transplantation Network/United Network for Organ Sharing (OPTN/UNOS) database. Mazzaferro and colleagues at Milan subsequently showed that survival rates were markedly improved when OLT was limited to patients with early-stage HCC (stage I or stage II) with one tumor ≤5 cm, or up to three tumors no larger than 3 cm, along with the absence of gross vascular invasion or extrahepatic spread. Multiple studies have validated these findings, and many groups have proposed an expansion of the Milan criteria.

As noted previously, the 6- to 40-point MELD score was adopted by OPTN/UNOS in 2002 for allocation of deceased donor liver organs in the United States. In an attempt to prioritize patients with preserved liver function and progressive HCC, patients with stage I or stage II HCC are allocated exception points (currently 22 MELD points, increasing every 3 months as long as they continue to meet transplant criteria). This allocation has had a positive effect for HCC liver transplant candidates, leading to decreased waiting list dropout and increased transplant rates with excellent long-term outcomes. The goal is to better equate death rates on the liver transplant waiting list for patients with stage I or stage II HCC with rates for patients with chronic liver disease without HCC. Although indications for liver transplantation have increased, the supply of donor livers has failed to keep pace with the numbers of potential recipients. A partial solution has been the use of living donor grafts. This is especially true in Asia where the incidence of HCC is high and the rate of cadaveric donation is low. Living donor grafts include right and left lobes, as well as dual grafts from separate donors to provide adequate hepatic mass to the recipient. The use of living donor grafts also allows for transplant programs to push the boundaries by accepting patients beyond the Milan criteria with good results.

Radiofrequency Ablation

In 1891, d’Arsonval discovered that radiofrequency (RF) waves delivered as an alternating electric current (>10 kHz) could pass through living tissue without causing pain or neuromuscular excitation. The resistance of the tissue to the rapidly alternating current produced heat. This discovery contributed to the development of the surgical application of electrocautery. In 1908, Beer used RF coagulation to destroy urinary bladder tumors. Cushing and Bovie later applied RF ablation to intracranial tumors. In 1961, Lounsberry studied the histologic changes of the liver after RF ablation (RFA) in animal models. He found that RF caused local tissue destruction with uniform necrosis. In the early 1990s, two groups proposed that RFA can be an effective method for destroying unresectable malignant liver tumors. Both groups found that RFA produced lesions with well-demarcated areas of necrosis without viable tumor cells present. Clinical reports after short-term follow-up suggested that RFA was safe and effective in the treatment of liver tumors. However, Abdalla and colleagues examined data for 358 consecutive patients with colorectal liver metastases treated with curative intent over a 10-year period (1992 to 2002). Liver-only recurrence after RFA was four times the rate after resection (44% vs. 11% of patients), and RFA alone or in combination with resection did not provide survival rates comparable to those with resection alone. Other studies have corroborated this trend. Nonetheless, RFA remains a common procedure that can be performed by a percutaneous, minimally invasive laparoscopic, or open approach. It also has been used successfully to ablate small HCCs as a bridge to liver transplantation.

Recently, results were reported for the first randomized clinical trial involving RFA treatment for HCC in 291 Chinese patients with three or fewer HCC tumors ranging in size from 3 to 7.5 cm. Patients were randomly assigned to treatment arms of RFA alone (n = 100), transarterial chemoembolization (TACE) alone (n = 95), or combined TACE plus RFA (n = 96). At a median follow-up of 28.5 months, median survival was 22 months in the RFA group, 24 months in the TACE group, and 37 months in the TACE plus RFA group. Patients treated with TACE plus RFA had significantly better overall survival than those treated with TACE alone (P < .001) or RFA alone (P < .001).

Ethanol Ablation, Cryosurgery, and Microwave Ablation

Percutaneous ethanol injection has been shown to be a safe and effective treatment for small HCCs. The ethanol usually is delivered by percutaneous injection under ultrasound or CT guidance. Percutaneous ethanol injection also is used to treat small HCC tumors as a bridge to liver transplantation in some centers to avoid patient dropout. Although cryosurgery was used in the late 1980s and 1990s for ablation of liver tumors, many have abandoned this approach in favor of RFA because of the latter’s fewer side effects and ease of use. Microwave ablation is a thermal ablative technique used in the management of unresectable liver tumors to produce a coagulation necrosis. In a multicenter phase II U.S. trial using a 915-MHz microwave generator, 87 patients underwent 94 ablation procedures for 224 hepatic tumors. Forty-five percent of the procedures were performed using an open approach, 7% laparoscopically, and 48% percutaneously. The average tumor size was 3.6 cm (range, 0.5 to 9.0 cm). At a mean follow-up of 19 months, 47% of the patients were alive with no evidence of disease. Local recurrence at the ablation site occurred in 2.7% of tumors, and regional recurrence occurred in 43% of patients. There were no procedure-related deaths. Further studies are required to define the role of this technology in relation to other ablation options available.

Chemoembolization and Hepatic Artery Pump Chemoperfusion

Chemoembolization is the process of injecting chemotherapeutic drugs combined with embolization particles into the hepatic artery that supplies the liver tumor using a percutaneous, transfemoral approach. It is most commonly used for treatment of unresectable HCC. Three randomized trials and a meta-analysis

CHAPTER 31
have shown a survival benefit with chemoembolization.\textsuperscript{125-128} In a study by Lo and colleagues, 80 Asian patients were randomly assigned to receive either chemoembolization with cisplatin in lipiodol or symptomatic treatment only.\textsuperscript{129} Chemoembolization resulted in a marked tumor response, and the actuarial survival was significantly better in the chemoembolization group (1- and 3-year survival of 57% and 26%, respectively) than in the control group (1- and 3-year survival of 32% and 3%, respectively). In another randomized trial, a Barcelona group compared chemoembolization with doxorubicin versus supportive care and showed that chemoembolization significantly improved survival.\textsuperscript{130} Finally, in a large prospective cohort study of 8510 patients with unresectable HCC in Japan who received transcatheter arterial lipiodol chemoembolization, the 5-year survival rate was 26% and median survival time was 34 months.\textsuperscript{131} The TACE-related mortality rate after the initial therapy was 0.5%. Complications of TACE include liver dysfunction or liver failure, hepatic abscess, and hepatic artery thrombosis. Multiple studies also have shown promising results for chemoembolization with drug-eluting beads in treatment of HCC.\textsuperscript{132}

In the 1990s, hepatic artery pump chemoperfusion with fluorouracil for colorectal cancer metastases to the liver was used both for treatment of inoperable disease and in the adjuvant setting.\textsuperscript{133} However, in the modern era of improved chemotherapeutic options, this treatment modality is seldom used outside of a clinical trial.

Yttrium-90 Microspheres

Selective internal radioembolization or transarterial radioembolization (TARE) is a promising new treatment modality for patients with inoperable primary or metastatic liver tumors. The treatment is a minimally invasive transcatheter therapy in which radioactive microspheres are infused into the hepatic arteries via a transfemoral percutaneous approach. The yttrium-90 microspheres are directly injected into the hepatic artery branches that supply the tumor. Once infused, the microspheres deliver doses of high-energy, low-penetration radiation selectively to the tumor. The main indications are inoperable HCC\textsuperscript{134} and colorectal cancer hepatic metastases for which systemic chemotherapy has failed.\textsuperscript{135,136} In a recent study involving 137 patients with unresectable chemo-refractory liver metastases treated with radioembolization, there was a response rate of 42.8% (2.1% complete response, 40.7% partial response) according to World Health Organization criteria.\textsuperscript{137} One-year survival rate was 47.8%, and 2-year survival rate was 30.9%. Median survival was 457 days for patients with colorectal tumor metastases, 776 days for those with neuroendocrine tumor metastases, and 207 days for those with noncolorectal, nonneuroendocrine tumor metastases. The two products available in the United States are SIR-Spheres (Sirtex, Sydney, Australia) and TheraSphere (Nordian, Ottawa, Canada).

Stereotactic Radiosurgery and Intensity-Modulated Radiation Therapy

Although stereotactic radiosurgery (with CyberKnife and other systems) is in widespread use for brain and spinal tumors, body application to HCC or metastatic liver tumors has only recently occurred. In a phase I study, 31 patients with unresectable HCCs and 10 with unresectable cholangiocarcinomas completed a six-fraction course of stereotactic body radiotherapy.\textsuperscript{138} The treatment was well tolerated, and median survival was 11.7 and 15.0 months for the two groups, respectively. A similar safety profile was observed in a study in the Netherlands.\textsuperscript{139} Further clinical trials are required to define the future role of stereotactic radiosurgery in treatment of HCC and metastatic tumors. Intensity-modulated radiation therapy (IMRT) is another technologic advancement that facilitates the targeted delivery of external-beam radiation. Early clinical data suggested favorable outcomes with IMRT for the treatment of patients with unresectable HCC, and ongoing trials are further examining the role of IMRT for these locally advanced tumors.

Downstaging

In more advanced-stage patients not eligible for MELD exception points, hepatic-directed therapy including TACE and tumor ablation with radiofrequency, microwave, and ethanol ablation have been found to be effective in shrinking tumors to meet Milan criteria (downstaging). Multiple centers have used downstaging to allow for OLT in patients whose tumors responded and shrank to meet eligibility criteria.\textsuperscript{136,137}

Systemic Chemotherapy

Chemotherapy has not demonstrated great efficacy in patients with HCC, especially in patients with significant cirrhosis. For treatment of HCC, the multikinase inhibitor sorafenib has shown some efficacy in a phase III randomized international multicenter trial. The SHARP trial (Sorafenib HCC Assessment Randomized Protocol) enrolled 602 patients with Child’s class A cirrhosis and inoperable HCC. At interim analysis, the trial was discontinued because a survival benefit was found in the treatment group. The median overall survival for patients receiving sorafenib was 10.7 months versus 7.9 months for patients in the control arm. Based on these findings, sorafenib received accelerated Food and Drug Administration approval for the treatment of advanced unresectable HCC.\textsuperscript{138} Future studies will likely examine the role of other molecularly targeted agents and combinations of sorafenib with other treatment modalities.

HEPATIC RESECTION SURGICAL TECHNIQUES

Nomenclature

Due to the confusion in language with regard to anatomic descriptions of hepatic resections, a common nomenclature was introduced at the International Hepato-Pancreato-Biliary Association meeting in Brisbane, Australia, in 2000 (Table 31-8).\textsuperscript{139,140} The goal was to provide universal terminology for liver anatomy and hepatic resections, because there was much overlap among the designations for hepatic lobes, sections, sectors, and segments used by surgeons worldwide (Fig. 31-21). The most common or prevailing anatomic pattern was used as the basis for naming liver anatomy, and the surgical procedure nomenclature adopted for hepatic resections was based on the assigned anatomic terminology.\textsuperscript{141} Adoption of a common language should enable hepatic surgeons to better understand and interpret liver surgery publications from different continents and disseminate their knowledge to the next generation of hepatobiliary surgeons. Nonetheless, even today, the literature is full of both old and new liver resection terminology, so the surgeon in training must be familiar with all the various classifications.

Techniques and Devices for Dividing the Hepatic Parenchyma

Hepatic resection surgery has evolved over the past 50 years. A better understanding of liver anatomy and physiology, coupled with improved anesthesia techniques and widespread use of
intraoperative ultrasound, has led to virtually “bloodless” liver surgery in the modern era (the year 2000 to the present). Innovations in technology have expanded the list of liver parenchymal transection devices and hemostatic agents (Table 31-9). Use of each device or agent has a learning curve, and undoubtedly every experienced hepatic surgeon has his or her personal preferences.

One major trend has been the application of vascular stapling devices for division of the hepatic and portal veins. Based on early reports of successful stapling of extrahepatic vessels, stapling devices are now being used in the parenchymal transection phase, which remains a source of potential blood loss due to back bleeding from the middle hepatic vein. One advantage of the stapling technique is the speed with which the transection can be performed, which minimizes surface bleeding and period of ischemia for the remnant liver. However, a major disadvantage of the stapling technique is the cost of multiple stapler cartridges. This is balanced by the decreased expenses reported with avoidance of ICU admission and blood transfusion, as well as shortened operating room time. Another consideration in the use of staplers for parenchymal transection is the potential for bile leaks. However, in a large series of 101 consecutive right hemihepatectomies performed using the stapling technique, there was only one reported bile leak (1%), which sealed after ERCP.

### Steps in Commonly Performed Hepatic Resections

A fundamental understanding of hepatic anatomy is vital for any surgeon with the desire to perform hepatobiliary surgery. Each hepatic resection surgery can be broken down into a

**Figure 31-21.** Hepatic anatomy. Hepatic segments removed in the formal major hepatic resections are indicated. IVC = inferior vena cava; LHV = left hepatic vein; MHV = middle hepatic vein; RHV = right hepatic vein.
Mastery of the operative steps coupled with knowledge of liver anatomy and the common anatomic variants provides the foundation for safe hepatic surgery. There are many different techniques and sequences for accomplishing each of the anatomic (and nonanatomic) hepatic operations. The authors present their preferred approach in a stepwise fashion for right hepatic lobectomy (right hemihepatectomy), left hepatic lobectomy (left hemihepatectomy), and left lateral segmentectomy (left lateral sectionectomy). Provision of a detailed approach for every type of liver resection is beyond the scope of this chapter, and readers are referred to several excellent descriptions.

**Steps Common to All Open Major Hepatic Resections**

1. Make the skin incision—right subcostal with or without a partial or complete left subcostal extension across the midline, depending on the patient’s habitus and liver/tumor anatomy.
2. Open and explore the abdomen, and place a fixed table retractor (e.g., Thompson or Bookwalter).
3. Examine the liver with bimanual palpation. Perform liver ultrasound, and confirm the operation to be performed.
4. Take down the round and falciform ligaments, and expose the anterior surface of the hepatic veins.
5. For a left hepatectomy, divide the left triangular ligament; for a right hepatectomy, mobilize the right lobe from the right coronary and triangular ligaments.
6. Open the gastrohepatic ligament, palpate the porta hepatis, and assess for accessory or replaced hepatic arteries.
7. Perform a cholecystectomy; leave the gallbladder with the cystic duct intact if the gallbladder is involved by the tumor.

**Right Hepatic Lobectomy (Right Hepatectomy or Hemihepatectomy)**

8. Mobilize the liver from the anterior aspect of the IVC in “piggyback” fashion; ligate the short hepatic veins up to the right hepatic vein (RHV).
9. Perform a right hilar dissection—gently lower the hilar plate, then doubly ligate and divide the right hepatic artery (RHA), superior to the right side of the common bile duct.
10. Doubly ligate and divide a replaced or accessory RHA if present.
11. Expose the portal vein, identifying its right and left branches. There is a small lateral portal vein branch off the right portal vein (RPV) to the caudate lobe that should be controlled and ligated to allow the exposure of additional length on the RPV. Divide the RPV either with a vascular stapler or between vascular clamps.
12. Dissect the avascular tissue along the suprahepatic vena cava between the right and middle hepatic veins. Pass a silastic tube of a Jackson-Pratt drain through this gap.
13. Notch or divide the caudate process crossing to the right hepatic lobe, and bring the drain up and through this notch.
14. Hang the liver over the drain by pulling up as you divide through the liver parenchyma.
15. Repeat ultrasound and confirm the transection plane, staying just to the right of the middle hepatic vein (MHV) unless the tumor extends over it.
16. Cauterize approximately 1 cm into the liver parenchyma, then switch to a hydro-jet dissection device in combination with Bovie electrocautery and suture ligation.
17. Continue parenchymal division until the RHV is encountered. During this division, identification, control, ligation, and transection of the right hepatic duct (RHD) are obtained late in the parenchymal transection process.
18. Divide the RHV between vascular clamps and suture ligate the RHV.
19. Examine the transected liver edge for bleeding; place a figure-of-eight ligating vascular suture if bleeding is encountered.
20. Ensure hemostasis of the transected liver edge with an argon beam coagulator and suture ligation.
21. Inspect the transection surface for bile leaks. These should be clipped or suture ligated. Applying a dilute solution of hydrogen peroxide can facilitate the visualization of bile leaks.
22. Inspect the IVC and right retroperitoneal space for hemostasis.
23. Perform completion ultrasound to confirm left portal vein (LPV) inflow and outflow in the remaining hepatic veins.
24. Fix the proximal falciform ligament back to the diaphragm side with figure-of-eight sutures.
25. Apply tissue sealant to the cut surface of the liver, and place a Jackson-Pratt drain in the right subphrenic space and close the abdomen (Fig. 31-22).

**Comments** Although some liver surgeons advocate a one-step division of the entire intrahepatic Glissonian pedicle as described by Launois and Jamieson, it is the authors’ preference to divide the RHA, RHD, and RPV in an extrhepatic fashion. As for the transection plane, the key is to perform...
accurate ultrasound visualization and mapping of the MHV and to stay just to the right of it. Weaving in and out or bisecting the MHV can lead to torrential back bleeding. Also, for bulky right lobe tumors adherent to the diaphragm or retroperitoneum, an anterior approach with division of the parenchyma can be performed before right lobe mobilization.\[sup\]12,13\[/sup]

**Left Hepatic Lobectomy (Left Hepatectomy or Hemihepatectomy)**

8. Widely open the gastrohepatic ligament flush with the undersurface of the left lateral section and the caudate lobe.
9. Doubly ligate and divide a replaced or accessory left hepatic artery (LHA) if present.
10. Clamp the round ligament (ligament teres) and pull it anteriorly as a handle to expose the left hilum.
11. Divide any existing parenchymal bridge between segments III and IVB.
12. Dissect the left hilum at the base of the umbilical fissure and lower the hilar plate anterior to the left portal pedicle.
13. Incise the peritoneum overlying the hilum from the left side, and doubly ligate the LHA (after test clamping and confirming a palpable pulse in the RHA).
14. Dissect the portal vein at the base of the umbilical fissure (it will take a nearly 90° bend from the transverse to the umbilical portion).
15. Expose the portal vein, identifying the right and left branches. Control the small portal vein branch off the LPV to the caudate lobe to allow the exposure of additional length. Divide the LPV either with a vascular stapler or between vascular clamps.
16. Ligate and divide the ligamentum venosum caudally.
17. Identify the long extrahepatic course of the left hepatic duct (LHD) behind the portal vein. Ligate and divide the LHD at the umbilical fissure.
18. Fold the left lateral segment up and back to the right, exposing the window at the base of the left hepatic vein (LHV) as it enters the IVC. This is facilitated by dividing any loose areolar tissue overlying the ligamentum venosum, which is divided proximally.
19. Pass a large, blunt right-angle clamp in the window between the RHV and the MHV, and hug the back of the MHV, aiming for the deep edge of the LHV. Do not force it or perforate the IVC or MHV.
20. Pass the silastic tube of a Jackson-Pratt drain through this window.
21. Notch or divide the caudate process crossing to the left hepatic lobe and bring the drain up and through this notch.
22. Hang the liver over the drain by pulling up as you divide through the liver parenchyma.
23. Repeat ultrasound and confirm the transection plane on the anterior surface, staying close to the demarcated line. Do not bisect the MHV as it passes tangentially from the left to the right lobe.
24. Cauterize down approximately 1 cm in the liver parenchyma, then switch to a hydro-jet dissection device in combination with Bovie electrocautery and suture ligation.
25. Continue parenchymal division until the left/middle hepatic veins are encountered.
26. Divide the LHV and MHV between vascular clamps and suture the ligate the LHV/MHV.

**Figure 31-23.** Completed left hepatic lobectomy (left hepatectomy) resecting segments II, III, and IV.

27. Check the transected edge of the liver for surgical bleeding; ensure hemostasis of the transected edge with an argon beam coagulator and suture ligation.
28. Inspect the transection surface for bile leaks. These should be clipped or suture ligated. Apply dilute solution of hydrogen peroxide to facilitate the visualization of bile leaks.
29. Perform completion ultrasound to confirm RPV inflow and RHV outflow.
30. Apply tissue sealant to the transected surface of the liver. Place a Jackson-Pratt drain in the left subphrenic space and close the abdomen (Fig. 31-23).

**Comments** Because the right posterior duct arises from the left hepatic duct (LHD) in approximately 20% of cases (see Fig. 31-9) and the right anterior duct comes off the LHD in approximately 5% of cases, \[sup\]5\[/sup] it is vital to divide the LHD at the base of the umbilical fissure and not more centrally in the hilum as it bifurcates. If the LHD were divided as it appears to bifurcate from the right hepatic duct, then approximately 20% to 25% of the time, either the right posterior or right anterior duct would be transected. After the LHD is divided as described earlier (Step 17), the liver parenchyma is scored and divided horizontally approximately 1 cm above the left hilum; the surgeon thus assumes that an aberrant right anterior or posterior duct is coming off the LHD in the hilum and preserves it. Then as the parenchymal transection reaches the left side of the gallbladder fossa, the transection plane turns vertical to run parallel to Cantlie’s line (or the left edge of the gallbladder bed). The left lobe of the liver will be well demarcated at this point (after the vascular inflow has been divided), which guides the transection plane on the anterior surface. In general, the transection plane should be close to the demarcation line to minimize the amount...
of devascularized liver remaining. When dividing the LHV and MHV, the surgeon should keep in mind that they have a common trunk approximately 90% of the time. If it is not easy to open the window deep to the MHV and LHV, then division of the MHV and LHV can be accomplished after the parenchymal transection.

**Left Lateral Segmentectomy (Left Lateral Sectionectomy)**

8. Widely open the gastrohepatic ligament flush with the undersurface of the left lateral section and the caudate lobe.
9. Doubly ligate and divide a replaced or accessory LHA if present.
10. Clamp the round ligament and pull it anteriorly as a handle to expose the left hilum.
11. Divide any existing parenchymal bridge between segments III and IVB.
12. Carry the dissection down from the end of the round ligament, and the segment III pedicle will be encountered.
13. Incise the peritoneal reflection on the left side of the round ligament as it inserts into the umbilical fissure. This will facilitate encircling the segment III and II pedicles, which can be divided separately. When encircling the segment II pedicle, take care to avoid injury to the caudate inflow vessels coming off the LPV.
14. Divide the liver parenchyma, staying flush on the left side of the falciform ligament using Bovie electrocautery.
15. Divide the LHV as the parenchymal transection is complete.
16. A Pringle maneuver usually is not required for a left lateral sectionectomy because complete devascularization occurs before transection and little back bleeding is encountered.

**Comments** If the segment III and II LHA branches are large, they can be individually ligated in the left hilum before the pedicles (with portal vein and hepatic duct branches) are taken. If the tumor is more peripheral in the left lateral segment, then the segment III and II pedicles can be divided with a vascular stapler inside the liver during the parenchymal transection.

**Pringle and Ischemic Preconditioning**

Pringle described clamping of the portal triad a century ago in the landmark paper “Notes on the Arrest of Hepatic Hemorrhage Due to Trauma.” Although the Pringle maneuver was initially described for controlling bleeding due to traumatic liver injury, it is commonly used during elective hepatic resections. The goal is to minimize blood loss and hypotension, which add significant morbidity to the operation. Furthermore, intraoperative blood transfusion has been shown to be an independent risk factor for increased postoperative infection as well as worse patient survival in some studies. Therefore, all efforts should be made to minimize blood loss during hepatic resection.

Although the liver has been shown to tolerate up to 1 hour of warm ischemia, some technical variations of the Pringle maneuver include intermittent vascular occlusion with cycles of approximately 15 minutes on and 5 minutes off. Experimental and clinical studies have demonstrated the efficacy of intermittent vascular occlusion in decreasing ischemia/reperfusion injury compared with continuous vascular occlusion, with less elevation of postoperative liver enzyme levels. Another variation is selective hemihepatic vascular occlusion, which can reduce the severity of visceral congestion and total liver ischemia. In one prospective trial of total versus selective portal triad clamping, both techniques of inflow clamping were found to be equally effective for patients with normal livers, but greater liver damage was observed with total inflow occlusion in patients with cirrhotic livers.

In an attempt to decrease the ischemic damage associated with inflow occlusion, some hepatic surgeons have advocated the use of ischemic preconditioning. Ischemic preconditioning refers to the brief interruption of blood flow to an organ, followed by a short reperfusion period, and then a more prolonged period of ischemia. In a randomized clinical trial involving 100 patients undergoing major hepatic resection, Clavien and colleagues reported significantly less liver injury in the group who received ischemic preconditioning with a 10-minute clamp, a 10-minute reperfusion, and then a 30-minute clamp than in those who received a 30-minute clamp alone. Patients with steatosis also were especially protected by ischemic preconditioning, and the mechanism was shown to be related in part to preservation of the adenosine triphosphate content of liver tissue.

**Preoperative Portal Vein Embolization**

The observation that tumor thrombosis of a major portal vein branch induced ipsilateral lobar atrophy and contralateral lobe hypertrophy led to the concept of intentional preoperative portal vein embolization (PVE) to induce compensatory hypertrophy of the remnant liver. This procedure was first described in the 1980s and is accomplished via a percutaneous, transhepatic route. Numerous studies have subsequently confirmed that PVE is effective in inducing hypertrophy of nonembolized hepatic segments. PVE usually is performed in the setting of a planned right trisectionectomy or extended left hepatectomy (also referred to as a left trisectionectomy; resection of Couinaud’s segments II, III, IV, V, and VIII of the liver) or extended hepatic lobectomy when it is thought that the patient’s remnant liver will be too small to support liver function. The future liver remnant volume (e.g., the volume of segments II, III, and I) in a patient undergoing a planned right trisectionectomy can be directly measured by helical CT and then divided by the total estimated liver volume to calculate the percentage of the future liver remnant. If the future liver remnant is thought to be too small, then PVE should be considered to increase the size of the future liver remnant. In general, surgery is planned approximately 4 weeks after PVE to allow adequate time for hypertrophy.

There is no universal agreement on what constitutes a future liver remnant adequate to avoid postoperative liver failure. It is thought that 25% to 30% of the total liver volume is adequate in patients with a normal liver. Vauthey and associates reported that major postoperative complications were increased when the estimated future liver remnant was <25%. Farges and colleagues conducted a prospective study to assess the benefits of PVE before right hepatectomy. They demonstrated that PVE had no beneficial effect on the postoperative course in patients with normal livers but significantly reduced postoperative complications in patients with chronic liver diseases. A larger remnant may be necessary even in patients with normal livers when a complex hepatectomy is planned or when the background liver is steatotic. This is especially relevant with the increased incidence of fatty liver disease. A larger remnant may also be needed when patients have received preoperative chemotherapy. Some have suggested that 40% of the total hepatic volume should remain to minimize postoperative complications in patients who have underlying liver disease or who have received preoperative chemotherapy for colorectal cancer metastases.
112 patients who underwent PVE, major complications, hepatic insufficiency, length of hospital stay, and 90-day mortality rate were significantly greater in patients with a standardized future liver remnant of ≤20% or a degree of hypertrophy of ≤5% than in patients with higher values.\textsuperscript{176} In another study, the authors performed PVE during neoadjuvant chemotherapy for colorectal cancer metastases. After a median wait of 30 days after PVE, patients receiving neoadjuvant chemotherapy showed median liver growth of 22% in the contralateral (nonembolized) lobe compared with 26% for those not receiving chemotherapy (not a statistically significant difference), which indicated that liver growth occurs after PVE even when cytotoxic chemotherapy is administered.\textsuperscript{177} PVE-related complications occur at a relatively low rate and include bleeding, hemobilia, liver abscess, incomplete embolization, and small bowel obstruction. To augment the ability to increase liver function reserve in patients who have undergone PVE, some groups have added ipsilateral hepatic artery embolization and ipsilateral hepatic vein embolization.\textsuperscript{172}

**Staged Hepatectomy and Repeat Hepatic Resection for Recurrent Liver Cancer**

A two-stage hepatectomy is a sequential resection strategy to remove all metastatic liver tumors when it is impossible to resect all disease in a single operative procedure. The first-stage hepatectomy usually consists of clearance of the left hemiliver by nonanatomic resection, followed by right portal vein ligation or embolization to induce left lobe hypertrophy.\textsuperscript{173,174} This is followed by a second-stage major right hepatectomy or extended right hepatectomy to resect the right liver metastases. This approach is most commonly used in cases of initially unresectable colorectal hepatic metastases and has yielded very good results.\textsuperscript{175} Another possibility is to potentiate the effect of PVE on increasing future liver remnant by performing an in situ liver transection along the future line of resection leaving the arterial and hepatic vein branches intact.\textsuperscript{175}

The majority of patients undergoing hepatic resection for colorectal cancer metastases experience a recurrence. For those with limited disease recurrence confined to the liver, repeat hepatectomy is a reasonable option and can be performed with low morbidity and mortality in experienced hands.\textsuperscript{176} In one study, 126 patients who underwent a second liver resection for colorectal cancer metastases had 1-, 3-, and 5-year survival rates of 86%, 51%, and 34%, respectively. By multivariate analysis, the presence of more than one lesion and a tumor size of >5 cm were independent prognostic indicators of reduced survival.\textsuperscript{177} In another study, 40 patients underwent a second hepatectomy for liver metastases from colorectal cancer and experienced a survival benefit similar to that from the first hepatectomy; however, the results suggested that this approach should be limited to those patients who do not have extrahepatic disease and for whom >1 year has elapsed since the first operation.\textsuperscript{178} A meta-analysis of 21 studies examining clinical outcomes after first and second liver resections for colorectal cancer metastases showed that repeat hepatectomy was safe and provided a survival benefit equal to that from the first liver resection.\textsuperscript{179}

Repeat hepatectomy also has been performed in patients with HCC. Nakajima and colleagues reported on follow-up of 94 patients who underwent curative liver resection for HCC from 1991 to 1996.\textsuperscript{180} Of these, 57 patients had isolated recurrent disease in the liver. Twelve of these 57 patients underwent repeat hepatic resection, whereas the other 45 patients received ablation therapy. The overall survival rate in those undergoing a second hepatectomy was 90% at 2 years; however, the disease-free survival rate was only 31% at 2 years, significantly lower than the 62% rate after initial hepatectomy. Likewise, in another group of 84 patients who underwent second hepatectomy for recurrent HCC, the overall 5-year survival rate was 50%, but the recurrence-free survival rate was only 10%.\textsuperscript{181} In a report of 67 patients undergoing a second resection for HCC, overall 1-, 3-, and 5-year survival rates were 93%, 70%, and 56%, respectively.\textsuperscript{182} Multivariate analysis showed that absence of portal invasion at the second resection, single HCC at primary hepatectomy, and disease-free interval of ≥1 year after primary hepatectomy were independent prognostic factors after the second resection.

**LAPAROSCOPIC LIVER RESECTION**

Cherqui and colleagues first reported in 2000 that laparoscopic hepatic surgery was feasible.\textsuperscript{183} Since this initial report, laparoscopic liver surgery has expanded from the simple unroofing of hepatic cysts to resection of peripheral benign lesions to formal anatomic lobectomies for malignancy and laparoscopic hepatectomy for living donor liver transplantation. While minimally invasive approaches have been widely adopted in other areas of abdominal surgery, there was initial apprehension regarding laparoscopic liver resection (LLR), hampering its widespread adoption.\textsuperscript{184} First, the elementary maneuvers of open hepatic surgery, such as manual palpation, organ mobilization, vascular control, and parenchymal transection, were thought to be difficult to reproduce laparoscopically. Second, there was concern that hemorrhage may be more difficult to control laparoscopically and that the risk of gas embolism may be increased by the use of pneumoperitoneum. Third, there was apprehension concerning the possibility of oncologic inadequacy and tumor seeding, but data regarding long-term oncologic outcomes were lacking at the time.

Because of the increased technical demands in LLR, stringent criteria based on surgeon experience and lesion size and location must be used. Surgeons should have an advanced understanding of liver anatomy, extensive experience in open liver surgery, and the technical skills to control major vascular and biliary structures laparoscopically before embarking on LLR. Familiarity with laparoscopic ultrasonography is needed to help confirm the number and size of lesions, demarcate transection planes, and define relationships to major intrahepatic and extrhepatic structures intraoperatively. Smaller, more peripheral lesions, particularly those located in the anterolateral segments (segments II to VI) are most amenable to LLR. Several centers have reported large series consisting of laparoscopic resections of the left lateral and anterior hepatic segments. Laparoscopic major hepatectomy, such as lobectomies, trisegmentectomies, and the resection of difficult posterior segments, has been described and can be performed by expert centers, but should not be considered standard practice at the current time.

As in open hepatic resections, various different technical approaches for performing major laparoscopic liver resection have been described. Hepatic resection can be achieved using either electrosurgical devices to transect the parenchyma, reserving staples for larger vascular and biliary structures, or staples alone to divide parenchyma and major structures without the aid of portal triad clamping. As in open liver surgery, no single method of parenchymal transection has been shown to be superior.
Three general techniques have been used for laparoscopic hepatectomy. The pure laparoscopic method is suitable for experienced surgeons to achieve better cosmetic outcomes, whereas the hand-assisted method has been associated with a reduced conversion rate to open procedures. The addition of the assisting hand allows for tactile feedback while palpating the liver and may help in abdominal exploration, parenchymal transection, mobilization of the liver, and providing gentle retraction. Additionally, in cases when significant bleeding is encountered, hand compression allows for easier hemostasis. The specimen is then removed from the hand-port incision. Hand assistance allows the laparoscopic approach to be extended to lesions in posterosuperior segments. Finally, the laparoscopic-assisted method, or the hybrid procedure, is used by surgeons for difficult or unique resections such as resection in cirrhotic livers, laparoscopic resection of tumors in unfavorable locations, and living donor hepatectomies. With the hybrid procedure, the liver is first mobilized laparoscopically, and the hilar dissection and parenchymal transection are then carried out under direct vision through an 8- to 12-cm midline or subcostal incision, through which the specimen is removed.

Results with laparoscopic liver resections have been excellent. Advantages of laparoscopic liver resection include reduced operative blood loss and need for portal triad clamping, decreased postoperative pain and narcotic requirements, faster return of bowel function, and shorter length of hospital stay. The actual occurrence of gas embolism in clinical practice has proven to be extremely low. Carbon dioxide pneumoperitoneum minimizes the risk of gas embolism as compared to air, and lowered pneumoperitoneum pressures further reduce its incidence. The occurrence of gas embolism has been also related to argon beam coagulation, which increases intra-abdominal pressure, leading to an increased risk of gas embolism.

Comparative studies between open resection and LLR for malignant lesions have revealed no difference in overall or disease-free survival after short- and medium-term follow-up, and no difference in the width of resection margins. Some series have even reported fewer positive resection margins with LLR compared to open resection for malignant lesions. No port site recurrences or tumor seeding has been reported to date after LLR. It has been proposed that LLR may allow for more timely start of adjuvant chemotherapy because of a quicker postoperative recovery and fewer wound-related complications.

In particular to LLR for HCC, hypothesized advantages include avoidance of collateral vessel ligation, resulting in reduced portal hypertension, decreased need for intravenous fluids, and improved reabsorption of ascites. The reduced occurrence of postoperative ascites and hepatic insufficiency in cirrhotic patients has led to decreased morbidity in these high-risk patients operated through a laparoscopic approach. The persisting underlying liver disease in these patients, however, dictates that HCC will recur in 40% to 90% of this population after resection, necessitating salvage liver transplantation. Laurent and colleagues reported that prior LLR for HCC compared to open resection facilitated subsequent salvage liver transplantation with decreased morbidity. In this study, patients with previous LLR had shorter hepatectomy and total operative times, less blood loss, and reduced need for blood transfusions after liver transplantation, possibly due to less arduous adhesiolysis. Zhou and colleagues published a meta-analysis of 10 nonrandomized controlled studies to compare surgical and oncologic outcomes following LLR or open resection for HCC. Compared with perioperative results of open liver resection, reports of LLR demonstrate advantageous outcomes related to blood loss, transfusion requirements, postoperative morbidity, and hospital length of stay. There were significantly lower rates of cirrhotic decompensation and ascites, as well as a trend toward lower rates of postoperative liver failure following LLR. There were no differences in operative time or postoperative mortality. With regard to specific oncologic outcomes, there were no differences in pathologic resection margin or in 3- and 5-year overall and disease-free survival. There were no reported cases of port site recurrences or peritoneal dissemination. This meta-analysis suggests that LLR is comparable, and in some parameters superior, to open resection for HCC.

Regarding LLR for metastatic colorectal cancer, multiple retrospective series have reported the safety, feasibility, and oncologic integrity of the laparoscopic approach. Castaing and colleagues reported a matched prospective comparison in patients undergoing resection of colorectal cancer liver metastases via laparoscopic and open approaches. There were no differences in resection margins, whereas the incidence of positive margins was greater in the open group. There were no differences in 1- or 3-year overall, recurrence-free, and disease-free survival, indicating that equivalent oncologic outcomes can be achieved with LLR in selected patients.

Initial experience with laparoscopic living-donor hepatectomy for transplantation was with left lateral segmentectomy during liver allograft procurement for pediatric transplants. With continued advances in laparoscopic liver surgery, this approach has been applied to adult-to-adult donor right hepatectomy using the hybrid procedure. Complication rates are comparable to those reported for open living-donor hepatectomies. Laparoscopic liver resection can now be performed safely by experienced surgeons in selected patients. Benefits of the laparoscopic approach include less operative blood loss, reduced postoperative pain and narcotic requirements, a shorter length of hospital stay, and comparable postoperative morbidity and mortality rates to open liver resection. Although small peripheral lesions in anterolateral segments are most amenable to laparoscopic resection, surgeons with extensive experience can embark on major hepatic resections using the laparoscopic approach. Comparative studies have identified similar oncologic outcomes for laparoscopic and open resections for malignant lesions such as HCC and colorectal liver metastases.

SPECIFIC CONSIDERATIONS

UNIT II

PART II

The gallbladder is lined by a single, highly folded, tall columnar epithelium that contains cholesterol and fat globules. The mucus secreted into the gallbladder originates in the tubuloalveolar glands found in the mucosa lining the infundibulum and neck of the gallbladder, but are absent from the body and fundus. The epithelial lining of the gallbladder is supported by a lamina propria. The muscle layer has circular longitudinal and oblique fibers, but without well-developed layers. The perimuscular subserosa contains connective tissue, nerves, vessels, lymphatics, and adipocytes. It is covered by the serosa except where the gallbladder is embedded in the liver. The gallbladder differs histologically from the rest of the gastrointestinal (GI) tract in that it lacks a muscularis mucosa and submucosa.

The cystic artery that supplies the gallbladder is usually a branch of the right hepatic artery (>90% of the time). The course of the cystic artery may vary, but it nearly always is found within the hepatocystic triangle, the area bound by the cystic duct, common hepatic duct, and the liver margin (triangle of Calot). When the cystic artery reaches the neck of the gallbladder, it divides into anterior and posterior divisions. Venous return is carried either through small veins that enter directly into the liver or, rarely, to a large cystic vein that carries blood back to the portal vein. Gallbladder lymphatics drain into nodes at the neck of the gallbladder. Frequently, a visible lymph node overlies the insertion of the cystic artery into the gallbladder wall. The nerves of the gallbladder arise from the vagus and from sympathetic branches that pass through the celiac plexus.
The preganglionic sympathetic level is T8 and T9. Impulses from the liver, gallbladder, and the bile ducts pass by means of sympathetic afferent fibers through the splanchnic nerves and mediate the pain of biliary colic. The hepatic branch of the vagus nerve supplies cholinergic fibers to the gallbladder, bile ducts, and liver. The vagal branches also have peptide-containing nerves containing agents such as substance P, somatostatin, enkephalins, and vasoactive intestinal polypeptide.5

**Bile Ducts**

The extrahepatic bile ducts consist of the right and left hepatic ducts, the common hepatic duct, the cystic duct, and the common bile duct or choledochus. The common bile duct enters the second portion of the duodenum through a muscular structure, the sphincter of Oddi.5

The left hepatic duct is longer than the right and has a greater propensity for dilatation as a consequence of distal obstruction. The two ducts join to form a common hepatic duct, close to their emergence from the liver. The common hepatic duct is 1 to 4 cm in length and has a diameter of approximately 4 mm. It lies in front of the portal vein and to the right of the hepatic artery. The common hepatic duct is joined at an acute angle by the cystic duct to form the common bile duct.

The length of the cystic duct is quite variable. It may be short or absent and have a high union with the hepatic duct, or long and run parallel, behind, or spiral to the main hepatic duct before joining it, sometimes as far as at the duodenum. Variations of the cystic duct and its point of union with the common hepatic duct are surgically important (Fig. 32-2). The segment of the cystic duct adjacent to the gallbladder neck bears a variable number of mucosal folds called the **spiral valves of Heister**. They do not have any valvular function but may make cannulation of the cystic duct difficult.

The common bile duct is about 7 to 11 cm in length and 5 to 10 mm in diameter. The upper third (supraduodenal portion) passes downward in the free edge of the hepatoduodenal ligament, to the right of the hepatic artery and anterior to the portal vein. The middle third (retroduodenal portion) of the common bile duct curves behind the first portion of the duodenum and diverges laterally from the portal vein and the hepatic arteries. The lower third (pancreatic portion) curves behind the head of the pancreas in a groove, or traverses through it and enters the second part of the duodenum. There, the pancreatic duct frequently joins it. The common bile duct runs obliquely downward...
within the wall of the duodenum for 1 to 2 cm before opening on a papilla of mucous membrane (ampulla of Vater), about 10 cm distal to the pylorus. The union of the common bile duct and the main pancreatic duct follows one of three configurations. In about 70% of people, these ducts unite outside the duodenal wall and traverse the duodenal wall as a single duct. In about 20%, they join within the duodenal wall and have a short or no common duct, but open through the same opening into the duodenum. In about 10%, they exit via separate openings into the duodenum. The sphincter of Oddi, a thick coat of circular smooth muscle, surrounds the common bile duct at the ampulla of Vater (Fig. 32-3). It controls the flow of bile, and in some cases pancreatic juice, into the duodenum.

The extrahepatic bile ducts are lined by a columnar mucosa with numerous mucous glands in the common bile duct. A fibroareolar tissue containing scant smooth muscle cells surrounds the mucosa. A distinct muscle layer is not present in the human common bile duct. The arterial supply to the bile ducts is derived from the gastroduodenal and the right hepatic arteries, with major trunks running along the medial and lateral walls of the common duct (sometimes referred to as 3 o’clock and 9 o’clock). These arteries anastomose freely within the duct walls. The density of nerve fibers and ganglia increases near the sphincter of Oddi, but the nerve supply to the common bile duct and the sphincter of Oddi is the same as for the gallbladder.1,2

Figure 32-2. Variations of the cystic duct anatomy. A. Low junction between the cystic duct and common hepatic duct. B. Cystic duct adherent to the common hepatic duct. C. High junction between the cystic and the common hepatic duct. D. Cystic duct drains into right hepatic duct. E. Long cystic duct that joins common hepatic duct behind the duodenum. F. Absence of cystic duct. G. Cystic duct crosses posterior to common hepatic duct and joins it anteriorly. H. Cystic duct courses anterior to common hepatic duct and joins it posteriorly.

Figure 32-3. The sphincter of Oddi.
Anomalies

The classic description of the extrahepatic biliary tree and its arteries applies only in about one third of patients. The gallbladder may have abnormal positions, be intrahepatic, be rudimentary, have anomalous forms, or be duplicated. Isolated congenital absence of the gallbladder is very rare, with a reported incidence of 0.03%. Before the diagnosis is made, the presence of an intrahepatic bladder or anomalous position must be ruled out. Duplication of the gallbladder with two separate cavities and two separate cystic ducts has an incidence of about one in every 4000 persons. This occurs in two major varieties: the more common form in which each gallbladder has its own cystic duct that empties independently into the same or different parts of the extrahepatic biliary tree, and as two cystic ducts that merge before they enter the common bile duct. Duplication is only clinically important when some pathologic processes affect one or both organs. A left-sided gallbladder with a cystic duct emptying into the left hepatic duct or the common bile duct and a retrodisplacement of the gallbladder are both extremely rare. A partial or totally intrahepatic gallbladder is associated with an increased incidence of cholelithiasis.

Small ducts (of Luschka) may drain directly from the liver into the body of the gallbladder. If present, but not recognized at the time of a cholecystectomy, a bile leak with the accumulation of bile (biloma) may occur in the abdomen. An accessory right hepatic duct occurs in about 5% of cases. Variations of how the common bile duct enters the duodenum are described in earlier, in the Bile Ducts section.

Anomalies of the hepatic artery and the cystic artery are quite common, occurring in as many as 50% of cases. In about 5% of cases, there are two right hepatic arteries, one from the common hepatic artery and the other from the superior mesenteric artery. In about 20% of patients, the right hepatic artery comes off the superior mesenteric artery. The right hepatic artery may be vulnerable during surgical procedures, in particular when it runs parallel to the cystic duct or in the mesentery of the gallbladder. The cystic artery arises from the right hepatic artery in about 90% of cases, but may arise from the left hepatic, common hepatic, gastroduodenal, or superior mesenteric arteries (Fig. 32-4).

PHYSIOLOGY

Bile Formation and Composition

The liver produces bile continuously and excretes it into the bile canaliculi. The normal adult consuming an average diet produces within the liver 500 to 1000 mL of bile a day. The secretion of bile is responsive to neurogenic, humoral, and chemical stimuli. Vagal stimulation increases secretion of bile, whereas splanchnic nerve stimulation results in decreased bile flow. Hydrochlooric acid, partly digested proteins, and fatty acids in the duodenum stimulate the release of secretin from the duodenum that, in turn, increases bile production and bile flow. Bile flows from the liver through to the hepatic ducts, into the common hepatic duct, through the common bile duct, and finally into the duodenum. With an intact sphincter of Oddi, bile flow is directed into the gallbladder.

Bile is mainly composed of water, electrolytes, bile salts, proteins, lipids, and bile pigments. Sodium, potassium, calcium, and chlorine have the same concentration in bile as in plasma or extracellular fluid. The pH of hepatic bile is usually neutral or slightly alkaline, but varies with diet; an increase in protein shifts the bile to a more acidic pH. The primary bile salts, cholate and chenodeoxycholate, are synthesized in the liver from cholesterol. They are conjugated there with taurine and glycine and act within the bile as anions (bile acids) that are balanced by sodium. Bile salts are excreted into the bile by the hepatocyte and aid in the digestion and absorption of fats in the intestines. In the intestines, about 80% of the conjugated bile acids are absorbed in the terminal ileum. The remainder is dehydroxylated (deconjugated) by gut bacteria, forming secondary bile acids deoxycholate and lithocholate. These are absorbed in the colon, transported to the liver, conjugated, and secreted into the bile. Eventually, about 95% of the bile acid pool is reabsorbed and returned via the portal venous system to the liver, the so-called enterohepatic circulation. Five percent is excreted in the stool, leaving the relatively small amount of bile acids to have maximum effect.
Cholesterol and phospholipids synthesized in the liver are the principal lipids found in bile. The synthesis of phospholipids and cholesterol by the liver is, in part, regulated by bile acids. The color of the bile is due to the presence of the pigment bilirubin diglucuronide, which is the metabolic product from the breakdown of hemoglobin and is present in bile in concentrations 100 times greater than in plasma. Once in the intestine, bacteria convert it into urobilinogen, a small fraction of which is absorbed and secreted into the bile.

**Galbladder Function**
The gallbladder, the bile ducts, and the sphincter of Oddi act together to store and regulate the flow of bile. The main function of the gallbladder is to concentrate and store hepatic bile and to deliver bile into the duodenum in response to a meal.

**Absorption and Secretion.** In the fasting state, approximately 80% of the bile secreted by the liver is stored in the gallbladder. This storage is made possible because of the remarkable absorptive capacity of the gallbladder, as the gallbladder mucosa has the greatest absorptive power per unit area of any structure in the body. It rapidly absorbs sodium, chloride, and water against significant concentration gradients, concentrating the bile as much as 10-fold and leading to a marked change in bile composition. This rapid absorption is one of the mechanisms that prevents a rise in pressure within the biliary system under normal circumstances. Gradual relaxation as well as emptying of the gallbladder during the fasting period also plays a role in maintaining a relatively low intraluminal pressure in the biliary tree.

The epithelial cells of the gallbladder secrete at least two important products into the gallbladder lumen: glycoproteins and hydrogen ions. The mucosal glands in the infundibulum and the neck of the gallbladder secrete mucus glycoproteins that are believed to protect the mucosa from the lytic action of bile and to facilitate the passage of bile through the cystic duct. This mucus makes up the colorless “white bile” seen in hydrops of the gallbladder resulting from cystic duct obstruction. The transport of hydrogen ions by the gallbladder epithelium leads to a decrease in the gallbladder bile pH. The acidification promotes calcium solubility, thereby preventing its precipitation as calcium salts.

**Motor Activity.** Gallbladder filling is facilitated by tonic contraction of the sphincter of Oddi, which creates a pressure gradient between the bile ducts and the gallbladder. During fasting, the gallbladder does not simply fill passively. In association with phase II of the interdigestive migrating myenteric motor complex in the gut, the gallbladder repeatedly empties small volumes of bile into the duodenum. This process is mediated at least in part by the hormone motilin. In response to a meal, the gallbladder empties by a coordinated motor response of gallbladder contraction and sphincter of Oddi relaxation. One of the main stimuli to gallbladder emptying is the hormone cholecystokinin (CCK). CCK is released endogenously from the duodenal mucosa in response to a meal. When stimulated by eating, the gallbladder empties 50% to 70% of its contents within 30 to 40 minutes. Over the following 60 to 90 minutes, the gallbladder gradually refills. This is correlated with a reduced CCK level. Other hormonal and neural pathways also are involved in the coordinated action of the gallbladder and the sphincter of Oddi. Defects in the motor activity of the gallbladder are thought to play a role in cholesterol nucleation and gallstone formation.

**Neurohormonal Regulation.** The vagus nerve stimulates contraction of the gallbladder, and splanchnic sympathetic stimulation is inhibitory to its motor activity. Parasympathomimetic drugs contract the gallbladder, whereas atropine leads to relaxation. Neuromediators reflexes link the sphincter of Oddi with the gallbladder, stomach, and duodenum to coordinate the flow of bile into the duodenum. Antral distention of the stomach causes both gallbladder contraction and relaxation of the sphincter of Oddi.

Hormonal receptors are located on the smooth muscles, vessels, nerves, and epithelium of the gallbladder. CCK is a peptide that comes from epithelial cells of the upper GI tract and is found in the highest concentrations in the duodenum. CCK is released into the bloodstream by acid, fat, and amino acids in the duodenum. CCK has a plasma half-life of 2 to 3 minutes and is metabolized by both the liver and the kidneys. CCK acts directly on smooth muscle receptors of the gallbladder and stimulates gallbladder contraction. It also relaxes the terminal bile duct, the sphincter of Oddi, and the duodenum. CCK stimulation of the gallbladder and the biliary tree also is mediated by cholinergic vagal neurons. In patients who have had a vagotomy, the response to CCK stimulation is diminished and the size and the volume of the gallbladder are increased.

Vasoactive intestinal polypeptide inhibits contraction and causes gallbladder relaxation. Somatostatin and its analogues are potent inhibitors of gallbladder contraction. Patients treated with somatostatin analogues and those with somatostatinoma have a high incidence of gallstones, presumably due to the inhibition of gallbladder contraction and emptying. Other hormones such as substance P and enkephalin affect gallbladder motility, but the physiologic role is unclear.

**Sphincter of Oddi**
The sphincter of Oddi regulates flow of bile (and pancreatic juice) into the duodenum, prevents the regurgitation of duodenal contents into the biliary tree, and diverts bile into the gallbladder. It is a complex structure that is functionally independent from the duodenal musculature and creates a high-pressure zone between the bile duct and the duodenum. The sphincter of Oddi is about 4 to 6 mm in length and has a basal resting pressure of about 13 mmHg above the duodenal pressure. On manometry, the sphincter shows phasic contractions with a frequency of about four per minute and an amplitude of 12 to 140 mmHg. The spontaneous motility of the sphincter of Oddi is regulated by the interstitial cells of Cajal through intrinsic and extrinsic inputs from hormones and neurons acting on the smooth muscle cells. Relaxation occurs with a rise in CCK, leading to diminished amplitude of phasic contractions and reduced basal pressure, allowing increased flow of bile into the duodenum (Fig. 32-5). During fasting, the sphincter of Oddi activity is coordinated with the periodic partial gallbladder emptying and an increase in bile flow that occurs during phase II of the migrating myoelectric motor complexes.

**Diagnostic Studies**

A variety of diagnostic modalities are available for the patient with suspected disease of the gallbladder and the bile ducts. In 1924, the diagnosis of gallstones was improved significantly by the introduction of oral cholecystography by Graham and Cole. For decades, it was the mainstay of investigation for gallstones. In the 1950s, biliary scintigraphy was developed, as well as intrahepatic and endoscopic retrograde cholangiography (ERC), allowing imaging of the biliary tract. Later ultrasonography,
Blood Tests
When patients with suspected diseases of the gallbladder or the extrahepatic biliary tree are evaluated, a complete blood count and liver function tests are routinely requested. An elevated white blood cell (WBC) count may indicate or raise suspicion of cholecystitis. If associated with an elevation of bilirubin, alkaline phosphatase, and aminotransferase, cholangitis should be suspected. Cholestasis, an obstruction to bile flow, is characterized by an elevation of bilirubin (i.e., the conjugated form) and an increase in alkaline phosphatase. Serum aminotransferases may be normal or mildly elevated. In patients with biliary colic or chronic cholecystitis, blood tests will typically be normal.

Ultrasonography
An ultrasound is the initial investigation of any patient suspected of disease of the biliary tree. It is noninvasive, painless, does not submit the patient to radiation, and can be performed on critically ill patients. It is dependent upon the skills and the experience of the operator, and it is dynamic (i.e., static images do not give the same information as those obtained during the ultrasound investigation itself). Adjacent organs can frequently be examined at the same time. Obese patients, patients with ascites, and patients with distended bowel may be difficult to examine satisfactorily with an ultrasound.

Ultrasound will show stones in the gallbladder with sensitivity and specificity of >90%. Stones are acoustically dense and reflect the ultrasound waves back to the ultrasonic transducer. Because stones block the passage of sound waves to the region behind them, they also produce an acoustic shadow (Fig. 32-6). Stones move with changes in position. Polyps may be calcified and reflect shadows, but do not move with change in posture. Some stones form a layer in the gallbladder; others a sediment or sludge. A thickened gallbladder wall and local tenderness indicate cholecystitis. The patient has acute cholecystitis if a layer of edema is seen within the wall of the gallbladder or between the gallbladder and the liver in association with localized tenderness. When a stone obstructs the neck of the gallbladder, the gallbladder may become very large, but thin walled. A contracted, thick-walled gallbladder is indicative of chronic cholecystitis.

The extrahepatic bile ducts are also well visualized by ultrasound, except for the retroduodenal portion. Dilation of the ducts in a patient with jaundice establishes an extrahepatic obstruction as a cause for the jaundice. Frequently, the site and, sometimes, the cause of obstruction can be determined by ultrasound. Small stones in the common bile duct frequently get lodged at the distal end of it, behind the duodenum, and are, therefore, difficult to detect. A dilated common bile duct on ultrasound, small stones in the gallbladder, and the clinical presentation allow one to assume that a stone or stones are causing the obstruction. Periampullary tumors can be difficult to diagnose on ultrasound, but beyond the retroduodenal portion, the level of obstruction and the cause may be visualized quite well. Ultrasound can be helpful in evaluating tumor invasion and flow in the portal vein, an important guideline for resectability of periampullary and pancreatic head tumors.

Oral Cholecystography
Once considered the diagnostic procedure of choice for gallstones, oral cholecystography has largely been replaced by ultrasonography. It involves oral administration of a radiopaque compound that is absorbed, excreted by the liver, and passed into the gallbladder. Stones are noted on a film as filling defects in a visualized, opacified gallbladder. Oral cholecystography is of no value in patients with intestinal malabsorption, vomiting, obstructive jaundice, and hepatic failure.
Biliary Radionuclide Scanning (HIDA Scan)

Biliary scintigraphy provides a noninvasive evaluation of the liver, gallbladder, bile ducts, and duodenum with both anatomic and functional information. 99mTc-technetium-labeled derivatives of dimethyl iminodiacetic acid (HIDA) are injected intravenously, cleared by the Kupffer cells in the liver, and excreted in the bile. Uptake by the liver is detected within 10 minutes, and the gallbladder, bile ducts, and the duodenum are visualized within 60 minutes in fasting subjects. The primary use of biliary scintigraphy is in the diagnosis of acute cholecystitis, which appears as a nonvisualized gallbladder, with prompt filling of the common bile duct and duodenum. Evidence of cystic duct obstruction on biliary scintigraphy is highly diagnostic for acute cholecystitis. The sensitivity and specificity for the diagnosis are about 95% each. False-positive results are increased in patients with gallbladder stasis, as in critically ill patients and in patients receiving parenteral nutrition. Filling of the gallbladder and common bile duct with delayed or absent filling of the duodenum indicates an obstruction at the ampulla. Biliary leaks as a complication of surgery of the gallbladder or the biliary tree can be confirmed and frequently localized by biliary scintigraphy.

Computed Tomography

Abdominal CT scans are inferior to ultrasonography in diagnosing gallstones. The major application of CT scans is to define the course and status of the extrahepatic biliary tree and adjacent structures. It is the test of choice in evaluating the patient with suspected malignancy of the gallbladder, the extrahepatic biliary system, or nearby organs, in particular, the head of the pancreas. Use of CT scan is an integral part of the differential diagnosis of obstructive jaundice (Fig. 32-7). Spiral CT scanning provides additional staging information, including vascular involvement in patients with periamplullary tumors.

Percutaneous Transhepatic Cholangiography

Intrahepatic bile ducts are accessed percutaneously with a small needle under fluoroscopic guidance. Once the position in a bile duct has been confirmed, a guidewire is passed, and subsequently, a catheter is passed over the wire (Fig. 32-8). Through the catheter, a cholangiogram can be performed and therapeutic interventions done, such as biliary drain insertions and stent placements. Percutaneous transhepatic cholangiography (PTC) has little role in the management of patients with uncomplicated gallstone disease but is particularly useful in patients with bile duct strictures and tumors, as it defines the anatomy of the biliary tree proximal to the affected segment. As with any invasive procedure, there are potential risks. For PTC, these are mainly bleeding, cholangitis, bile leak, and other catheter-related problems.

Magnetic Resonance Imaging

Available since the mid-1990s, MRI provides anatomic details of the liver, gallbladder, and pancreas similar to those obtained from CT. Many MRI techniques (i.e., heavily T2-weighted sequences, pulse sequences with or without contrast materials) can generate high-resolution anatomic images of the biliary tree and the pancreatic duct. It has a sensitivity and specificity of 95% and 89%, respectively, at detecting cholechocholithiasis. MRI with magnetic resonance cholangiopancreatography (MRCP) offers a single noninvasive test for the diagnosis of biliary tract and pancreatic disease (Fig. 32-9). In many centers, MRCP is first performed for diagnosis of biliary and pancreatic duct pathology, reserving endoscopic retrograde cholangiopancreatography (ERCP) for therapeutic purposes only.

Endoscopic Retrograde Cholangiopancreatography

Using a side-viewing endoscope, the common bile duct can be cannulated and a cholangiogram performed using fluoroscopy (Fig. 32-10). The procedure requires intravenous (IV) sedation for the patient. The advantages of ERC include direct visualization of the ampullary region and direct access to the distal common bile duct, with the possibility of therapeutic intervention. The test is rarely needed for uncomplicated gallstone disease, but for stones in the common bile duct, in particular, when associated with obstructive jaundice, cholangitis, or gallstone pancreatitis, ERC is the diagnostic and often therapeutic procedure of choice. Once the endoscopic cholangiogram has shown ductal stones, sphincterotomy and stone extraction can be performed, and the common bile duct cleared of stones. In the hands of experts, the success rate of common bile duct cannulation and cholangiography is >90%. Complications of diagnostic ERC include pancreatitis and cholangitis and occur in up to 5% of patients. The development of small fiber-optic cameras that can be threaded through endoscopes used for endoscopic retrograde cholangiopancreatography (ERCP) has facilitated the development of intraductal endoscopy. By providing direct visualization of the biliary and pancreatic ducts, this technology has been shown to increase the effectiveness of ERCP in the diagnosis of certain biliary and pancreatic diseases.

Intraductal endoscopy has been shown to have therapeutic applications that include biliary stone lithotripsy and extraction in high-risk surgical patients. As with most endoscopic procedures, intraductal endoscopy generally is considered safe, but...
there are no large trials that specifically address this issue. Typical complications such as bile duct perforation, minor bleeding from sphincterotomy or lithotripsy, and cholangitis have been described. Further refinement of this technology will enhance ERCP as a diagnostic and therapeutic tool.

**Endoscopic Ultrasound**

Endoscopic ultrasound requires a special endoscope with an ultrasound transducer at its tip. The results are operator dependent, but offer noninvasive imaging of the bile ducts and adjacent structures. It is of particular value in the evaluation of tumors and their resectability. The ultrasound endoscope has a biopsy channel, allowing needle biopsies of a tumor under ultrasonic guidance. Endoscopic ultrasound also has been used to identify bile duct stones, and although it is less sensitive than ERC, the technique is less invasive as cannulation of the sphincter of Oddi is not necessary for diagnosis of choledocholithiasis.

**GALLSTONE DISEASE**

**Prevalence and Incidence**

Gallstone disease is one of the most common problems affecting the digestive tract. Autopsy reports have shown a prevalence of gallstones from 11% to 36%. The prevalence of gallstones is related to many factors, including age, gender,
and ethnic background. Certain conditions predispose to the development of gallstones. Obesity, pregnancy, dietary factors, Crohn’s disease, terminal ileal resection, gastric surgery, hereditary spherocytosis, sickle cell disease, and thalassemia are all associated with an increased risk of developing gallstones. Women are three times more likely to develop gallstones than men, and first-degree relatives of patients with gallstones have a twofold greater prevalence.

Natural History
Most patients will remain asymptomatic from their gallstones throughout life. For unknown reasons, some patients progress to a symptomatic stage, with biliary colic caused by a stone obstructing the cystic duct. Symptomatic gallstone disease may progress to complications related to the gallstones. These include acute cholecystitis, choledocholithiasis with or without cholangitis, gallstone pancreatitis, cholecystocholedochal fistula, cholecystoduodenal or cholecystoenteric fistula leading to gallstone ileus, and gallbladder carcinoma. Rarely, complication of gallstones is the presenting picture.

Gallstones in patients without biliary symptoms are commonly diagnosed incidentally on ultrasonography, CT scans, or abdominal radiography or at laparotomy. Several studies have examined the likelihood of developing biliary colic or developing significant complications of gallstone disease. Approximately 3% of asymptomatic individuals become symptomatic per year (i.e., develop biliary colic). Once symptomatic, patients tend to have recurring bouts of biliary colic. Complicated gallstone disease develops in 3% to 5% of symptomatic patients per year. Over a 20-year period, about two thirds of asymptomatic patients with gallstones remain symptom free.

Because few patients develop complications without previous biliary symptoms, prophylactic cholecystectomy in asymptomatic persons with gallstones is rarely indicated. For elderly patients with diabetes, for individuals who will be isolated from medical care for extended periods of time, and in populations with increased risk of gallbladder cancer, prophylactic cholecystectomy may be advisable. Porcelain gallbladder, a rare premalignant condition in which the wall of the gallbladder...
gallbladder becomes calcified, is an absolute indication for cholecystectomy.

**Gallstone Formation**

Gallstones form as a result of solids settling out of solution. The major organic solutes in bile are bilirubin, bile salts, phospholipids, and cholesterol. Gallstones are classified by their cholesterol content as either cholesterol stones or pigment stones. Pigment stones can be further classified as either black or brown. In Western countries, about 80% of gallstones are cholesterol stones and about 15% to 20% are black pigment stones. Brown pigment stones account for only a small percentage. Both types of pigment stones are more common in Asia.

**Cholesterol Stones.** Pure cholesterol stones are uncommon and account for <10% of all stones. They usually occur as single large stones with smooth surfaces. Most other cholesterol stones contain variable amounts of bile pigments and calcium, but are always >70% cholesterol by weight. These stones are usually multiple, of variable size, and may be hard and faceted or irregular, mulberry-shaped, and soft (Fig. 32-11). Colors range from whitish yellow and green to black. Most cholesterol stones are radiolucent; <10% are radiopaque. Whether pure or of mixed nature, the common primary event in the formation of cholesterol stones is supersaturation of bile with cholesterol. Therefore, high bile cholesterol levels and cholesterol gallstones are considered as one disease. Cholesterol is highly nonpolar and insoluble in water and bile. Cholesterol solubility depends on the relative concentration of cholesterol, bile salts, and lecithin (the main phospholipid in bile). Supersaturation almost always is caused by cholesterol hypersecretion rather than by a reduced secretion of phospholipid or bile salts.

Cholesterol is secreted into bile as cholesterol-phospholipid vesicles. Cholesterol is held in solution by micelles, a conjugated bile salt-phospholipid-cholesterol complex, as well as by the cholesterol-phospholipid vesicles. The presence of vesicles and micelles in the same aqueous compartment allows the movement of lipids between the two. Vesicular maturation occurs when vesicular lipids are incorporated into micelles. Vesicular phospholipids are incorporated into micelles more readily than vesicular cholesterol. Therefore, vesicles may become enriched in cholesterol, become unstable, and then nucleate cholesterol crystals. In unsaturated bile, cholesterol enrichment of vesicles is inconsequential. In the supersaturated bile, cholesterol-dense zones develop on the surface of the cholesterol-enriched vesicles, leading to the appearance of cholesterol crystals. About one third of biliary cholesterol is transported in micelles; but the cholesterol-phospholipid vesicles carry the majority of biliary cholesterol (Fig. 32-12).

**Pigment Stones.** Pigment stones contain <20% cholesterol and are dark because of the presence of calcium bilirubinate. Otherwise, black and brown pigment stones have little in common and should be considered as separate entities.

Black pigment stones are usually small, brittle, black, and sometimes spiculated. They are formed by supersaturation of calcium bilirubinate, carbonate, and phosphate, most often secondary to hemolytic disorders such as hereditary spherocytosis and sickle cell disease, and in those with cirrhosis. Like cholesterol stones, they almost always form in the gallbladder. Unconjugated bilirubin is much less soluble than conjugated bilirubin in bile. Deconjugation of bilirubin occurs normally in bile at a slow rate. Excessive levels of conjugated bilirubin, as in hemolytic states, lead to an increased rate of production of unconjugated bilirubin. Cirrhosis may lead to increased secretion of unconjugated bilirubin. When altered conditions lead to increased levels of deconjugated bilirubin in bile, precipitation with calcium occurs. In Asian countries such as Japan, black stones account for a much higher percentage of gallstones than in the Western hemisphere.

Brown stones are usually <1 cm in diameter, brownish-yellow, soft, and often mushy. They may form either in the gallbladder or in the bile ducts, usually secondary to bacterial
infection caused by bile stasis. Precipitated calcium bilirubinate and bacterial cell bodies compose the major part of the stone. Bacteria such as Escherichia coli secrete β-glucuronidase that enzymatically cleaves bilirubin glucuronide to produce the insoluble unconjugated bilirubin. It precipitates with calcium, and along with dead bacterial cell bodies, forms soft brown stones in the biliary tree.

Brown stones are typically found in the biliary tree of Asian populations and are associated with stasis secondary to parasite infection. In Western populations, brown stones occur as primary bile duct stones in patients with biliary strictures or other common bile duct stones that cause stasis and bacterial contamination.

**Symptomatic Gallstones**

**Chronic Cholecystitis (Biliary Colic)**. About two thirds of patients with gallstone disease present with chronic cholecystitis characterized by recurrent attacks of pain, often inaccurately labeled biliary colic. The pain develops when a stone obstructs the cystic duct, resulting in a progressive increase of tension in the gallbladder wall. The pathologic changes, which often do not correlate well with symptoms, vary from an apparently normal gallbladder with minor chronic inflammation in the mucosa, to a shrunken, nonfunctioning gallbladder with gross transmural fibrosis and adhesions to nearby structures. The mucosa is initially normal or hypertrophied, but later becomes atrophied, with the epithelium protruding into the muscle coat, leading to the formation of the so-called Aschoff-Rokitansky sinuses.

**Clinical Presentation** The chief symptom associated with symptomatic gallstones is pain. The pain is constant and increases in severity over the first half hour or so and typically lasts 1 to 5 hours. It is located in the epigastrium or right upper quadrant and frequently radiates to the right upper back or between the scapulae (Fig. 32-13). The pain is severe and comes on abruptly, typically during the night or after a fatty meal. It often is associated with nausea and sometimes vomiting. The pain is episodic. The patient suffers discrete attacks of pain, between which they feel well. Physical examination may reveal mild right upper quadrant tenderness during an episode of pain. If the patient is pain free, the physical examination is usually unremarkable. Laboratory values, such as WBC count and liver function tests, are usually normal in patients with uncomplicated gallstones.

Atypical presentation of gallstone disease is common. Association with meals is present in only about 50% of patients. Some patients report milder attacks of pain, but relate it to meals. The pain may be located primarily in the back or the left upper or lower right quadrant. Bloating and belching may be present and associated with the attacks of pain. In patients with atypical presentation, other conditions with upper abdominal pain should be sought out, even in the presence of gallstones. These include peptic ulcer disease, gastroesophageal reflux disease, abdominal wall hernias, irritable bowel disease, diverticular disease, liver diseases, renal calculi, pleuritic pain, and myocardial pain. Many patients with other conditions have gallstones.

When the pain lasts >24 hours, an impacted stone in the cystic duct or acute cholecystitis (see later Acute Cholecystitis section) should be suspected. An impacted stone without cholecystitis will result in what is called hydrops of the gallbladder. The bile gets absorbed, but the gallbladder epithelium continues to secrete mucus, and the gallbladder becomes distended with mucinous material. The gallbladder may be palpable but usually is not tender. Hydrops of the gallbladder may result in edema of the gallbladder wall, inflammation, infection, and perforation. Although hydrops may persist with few consequences, early cholecystectomy is generally indicated to avoid complications.

**Diagnosis** The diagnosis of symptomatic gallstones or chronic calculous cholecystitis depends on the presence of typical symptoms and the demonstration of stones on diagnostic imaging. An abdominal ultrasound is the standard diagnostic test for gallstones (see earlier Ultrasonography section). Gallstones are occasionally identified on abdominal radiographs or CT scans. In these cases, if the patient has typical symptoms, an ultrasound of the gallbladder and the biliary tree should be added before surgical intervention. Stones diagnosed incidentally in patients without symptoms should be left in place as discussed previously in the Natural History section. Occasionally, patients with typical attacks of biliary pain have no evidence of stones on ultrasonography. Sometimes only sludge in the gallbladder...
is demonstrated on ultrasonography. If the patient has recurrent attacks of typical biliary pain and sludge is detected on two or more occasions, cholecystectomy is warranted. In addition to sludge and stones, cholesterolosis and adenomyomatosis of the gallbladder may cause typical biliary symptoms and may be detected on ultrasonography. Cholesterolosis is caused by the accumulation of cholesterol in macrophages in the gallbladder mucosa, either locally or as polyps. It produces the classic macroscopic appearance of a “strawberry gallbladder.” Adenomyomatosis or cholecystitis glandularis proliferans is characterized on microscopy by hypertrophic smooth muscle bundles and by the ingrowths of mucosal glands into the muscle layer (epithelial sinus formation). Granulomatous polypos develop in the lumen at the fundus, and the gallbladder wall is thickened and septae or strictures may be seen in the gallbladder. In symptomatic patients, cholecystectomy is the treatment of choice for patients with these conditions.  

Management Patients with symptomatic gallstones should be advised to have elective laparoscopic cholecystectomy. While waiting for surgery, or if surgery has to be postponed, the patient should be advised to avoid dietary fats and large meals. Diabetic patients with symptomatic gallstones should have a cholecystectomy promptly, as they are more prone to develop acute cholecystitis that is often severe. Pregnant women with symptomatic gallstones who cannot be managed expectantly with diet modifications can safely undergo laparoscopic cholecystectomy during the second trimester. Laparoscopic cholecystectomy is safe and effective in children as well as in the elderly. Cholecystectomy, open or laparoscopic, for patients with symptomatic gallstones offers excellent long-term results. About 90% of patients with typical biliary symptoms and stones are rendered symptom free after cholecystectomy. For patients with atypical symptoms or dyspepsia (flatulence, belching, bloating, and dietary fat intolerance), the results are not as favorable.

Acute Cholecystitis

Pathogenesis Acute cholecystitis is secondary to gallstones in 90% to 95% of cases. Acute acalculous cholecystitis is a condition that typically occurs in patients with other acute systemic diseases (see later Acalculous Cholecystitis section). In <1% of acute cholecystitis, the cause is a tumor obstructing the cystic duct. Obstruction of the cystic duct by a gallstone is the initiating event that leads to gallbladder distention, inflammation, and edema of the gallbladder wall. Why inflammation develops only occasionally with cystic duct obstruction is unknown. It is probably related to the duration of obstruction of the cystic duct. Initially, acute cholecystitis is an inflammatory process, probably mediated by the mucosal toxin lysolecithin, a product of lecithin, as well as bile salts and platelet-activating factor. Increase in prostaglandin synthesis amplifies the inflammatory response. Secondary bacterial contamination is documented in 15% to 30% of patients undergoing cholecystectomy for acute uncomplicated cholecystitis. In acute cholecystitis, the gallbladder wall becomes grossly thickened and reddish with suberosal hemorrhages. Pericholecystic fluid often is present. The mucosa may show hyperemia and patchy necrosis. In severe cases, about 5% to 10%, the inflammatory process progresses and leads to ischemia and necrosis of the gallbladder wall. More frequently, the gallstone is dislodged and the inflammation resolves.  

When the gallbladder remains obstructed and secondary bacterial infection supervenes, an acute gangrenous cholecystitis develops, and an abscess or empyema forms within the gallbladder. Rarely, perforation of ischemic areas occurs. The perforation is usually contained in the subhepatic space by the omentum and adjacent organs. However, free perforation with peritonitis, intrahepatic perforation with intrahepatic abscesses, and perforation into adjacent organs (duodenum or colon) with cholecystoenteric fistula occur. When gas-forming organisms are part of the secondary bacterial infection, gas may be seen in the gallbladder lumen and in the wall of the gallbladder on abdominal radiographs and CT scans, an entity called an emphysematous gallbladder.

Clinical Manifestations About 80% of patients with acute cholecystitis give a history compatible with chronic cholecystitis. Acute cholecystitis begins as an attack of biliary colic, but in contrast to biliary colic, the pain does not subside; it is unremitting and may persist for several days. The pain is typically in the right upper quadrant or epigastrium and may radiate to the right upper part of the back or the interscapular area. It is usually more severe than the pain associated with uncomplicated biliary colic. The patient is often febrile, complains of anorexia, nausea, and vomiting, and is reluctant to move, as the inflammatory process affects the parietal peritoneum. On physical examination, focal tenderness and guarding are usually present in the right upper quadrant. A mass, the gallbladder and adherent omentum, is occasionally palpable; however, guarding may prevent this. A Murphy’s sign, an inspiratory arrest with deep palpation in the right subcostal area, is characteristic of acute cholecystitis.

A mild to moderate leukocytosis (12,000–15,000 cells/mm³) is usually present. However, some patients may have a normal WBC. A high WBC count (above 20,000) is suggestive of a complicated form of cholecystitis such as gangrenous cholecystitis, perforation, or associated cholangitis. Serum liver chemistries are usually normal, but a mild elevation of serum bilirubin, <4 mg/dL, may be present along with mild elevation of alkaline phosphatase, transaminases, and amylase. Severe jaundice is suggestive of common bile duct stones or obstruction of the bile ducts by severe pericholecystic inflammation secondary to impaction of a stone in the infundibulum of the gallbladder that mechanically obstructs the bile duct (Mirizzi’s syndrome). In elderly patients and in those with diabetes mellitus, acute cholecystitis may have a subtle presentation resulting in a delay in diagnosis. The incidence of complications is higher in these patients, who also have approximately 10-fold the mortality rate compared to that of younger and healthier patients.

The differential diagnosis for acute cholecystitis includes a peptic ulcer with or without perforation, pancreatitis, appendicitis, hepatitis, perihepatitis (Fitz-Hugh–Curtis syndrome), myocardial ischemia, pneumonia, pleuritis, and herpes zoster involving the intercostal nerve.

Diagnosis Ultrasonography is the most useful radiologic test for diagnosing acute cholecystitis. It has a sensitivity and specificity of 95%. In addition to being a sensitive test for documenting the presence or absence of stones, it will show the thickening of the gallbladder wall and the pericholecystic fluid (Fig. 32-14). Focal tenderness over the gallbladder when compressed by the sonographic probe (sonographic Murphy’s sign) also is suggestive of acute cholecystitis. Biliary radionuclide scanning (HIDA scan) may be of help in the atypical case. Lack of filling of the gallbladder after 4 hours indicates an obstructed cystic duct and, in the clinical setting of acute cholecystitis, is highly sensitive and specific for acute cholecystitis. A normal
Cholecystitis is a condition in which the gallbladder becomes inflamed. It is most common in adults, affecting about 1% of the population in the Western world. The cause of cholecystitis is often the presence of gallstones, which can become lodged in the cystic duct or pass through it, causing inflammation of the gallbladder wall.

HIDA scan excludes acute cholecystitis. CT scan is frequently performed on patients with acute abdominal pain. It demonstrates thickening of the gallbladder wall, pericholecystic fluid, and the presence of gallstones as well as air in the gallbladder wall, but is less sensitive than ultrasonography.

**Treatment** Patients who present with acute cholecystitis will need IV fluids, antibiotics, and analgesia. The antibiotics should cover gram-negative aerobes as well as anaerobes. A third-generation cephalosporin with good anaerobic coverage or a second-generation cephalosporin combined with metronidazole is a typical regimen. For patients with allergies to cephalosporins, an aminoglycoside with metronidazole is appropriate. Although the inflammation in acute cholecystitis may be sterile in some patients, more than one half will have positive cultures from the gallbladder bile. It is difficult to know who is secondarily infected; therefore, antibiotics have become a part of the management in most medical centers.

Cholecystectomy is the definitive treatment for acute cholecystitis. In the past, the timing of cholecystectomy has been a matter of debate. Early cholecystectomy performed within 2 to 3 days of the illness is preferred over interval or delayed cholecystectomy that is performed 6 to 10 weeks after initial medical treatment and recuperation. Several studies have shown that unless the patient is unfit for surgery, early cholecystectomy should be recommended, as it offers the patient a definitive solution in one hospital admission, quicker recovery times, and an earlier return to work.

Laparoscopic cholecystectomy is the procedure of choice for acute cholecystitis. The conversion rate to an open cholecystectomy is higher (10%–15%) in the setting of acute cholecystitis than with chronic cholecystitis. The procedure is more tedious and takes longer than in the elective setting. However, when compared to the delayed operation, early operation carries a similar complication rate.

When patients present late, after 3 to 4 days of illness, or if they are unfit for surgery, they can be treated with antibiotics with laparoscopic cholecystectomy scheduled for approximately 2 months later. Approximately 20% of patients will fail to respond to initial medical therapy and require an intervention. Laparoscopic cholecystectomy could be attempted, but the conversion rate is high and some prefer to go directly for an open cholecystectomy. For those unfit for surgery, a percutaneous cholecystostomy or an open cholecystostomy under local analgesia can be performed. Failure to improve after cholecystostomy usually is due to gangrene of the gallbladder or perforation. For these patients, surgery is unavoidable. For those who respond after cholecystostomy, the tube can be removed once cholangiography through it shows a patent ductus cysticus. Laparoscopic cholecystectomy may then be scheduled in the near future. For the rare patients who can’t tolerate surgery, the stones can be extracted via the cholecystostomy tube before its removal.

**Choleodocholithiasis.** Common bile duct stones may be small or large and single or multiple, and are found in 6% to 12% of patients with stones in the gallbladder. The incidence increases with age. About 20% to 25% of patients above the age of 60 with symptomatic gallstones have stones in the common bile duct as well as in the gallbladder. The vast majority of ductal stones in Western countries are formed within the gallbladder and migrate down the cystic duct to the common bile duct. These are classified as secondary common bile duct stones, in contrast to the primary stones that form in the bile ducts. The secondary stones are usually cholesterol stones, whereas the primary stones are usually of the brown pigment type. The primary stones are associated with biliary stasis and infection and are more commonly seen in Asian populations. The causes of biliary stasis that lead to the development of primary stones include biliary stricture, papillary stenosis, tumors, or other (secondary) stones.

**Clinical Manifestations** Choledochal stones may be silent and often are discovered incidentally. They may cause obstruction, complete or incomplete, or they may manifest with cholangitis or gallstone pancreatitis. The pain caused by a stone in the bile duct is very similar to that of biliary colic caused by impaction of a stone in the cystic duct. Nausea and vomiting are common. Physical examination may be normal, but mild epigastric or right upper quadrant tenderness as well as mild icterus are common. The symptoms may also be intermittent, such as pain and transient jaundice caused by a stone that temporarily impacts the ampulla but subsequently moves away, acting as a ball valve. A small stone may pass through the ampulla spontaneously with resolution of symptoms. Finally, the stones may become completely impacted, causing severe progressive jaundice. Elevation of serum bilirubin, alkaline phosphatase, and transaminases are commonly seen in patients with bile duct stones. However, in about one third of patients with common bile duct stones, the liver chemistries are normal.

Commonly, the first test, ultrasonography, is useful for documenting stones in the gallbladder (if still present), as well as determining the size of the common bile duct. As stones in the bile ducts tend to move down to the distal part of the common duct, bowel gas can preclude their demonstration on ultrasonography. A dilated common bile duct (>8 mm in diameter) on ultrasonography in a patient with gallstones, jaundice, and biliary pain is highly suggestive of common bile duct stones. Magnetic resonance cholangiography (MRC) provides excellent anatomic detail and has a sensitivity and specificity of 95% and 89%, respectively, at detecting choleodocholithiasis >5 mm in diameter. Endoscopic cholangiography is the gold standard for diagnosing common bile duct stones. It has the distinct advantage of providing a therapeutic option at the time of diagnosis. In experienced hands, cannulation of the ampulla of Vater and diagnostic cholangiography are achieved in >90% of cases, with...
associated morbidity of <5% (mainly cholangitis and pancreatitis). Endoscopic ultrasound has been demonstrated to be as good as ERCP for detecting common bile duct stones (sensitivity of 91% and specificity of 100%), but it lacks therapeutic intervention and requires expertise, making it less available. PTC is rarely needed in patients with secondary common bile duct stones but is frequently performed for both diagnostic and therapeutic reasons in patients with primary bile duct stones.

**Treatment** For patients with symptomatic gallstones and suspected common bile duct stones, either preoperative endoscopic cholangiography or an intraoperative cholangiogram will document the bile duct stones. If an endoscopic cholangiogram reveals stones, sphincterotomy and ductal clearance of the stones is appropriate, followed by a laparoscopic cholecystectomy. An intraoperative cholangiogram at the time of cholecystectomy will also document the presence or absence of bile duct stones (Fig. 32-15).

Laparoscopic common bile duct exploration via the cystic duct or with formal choledochotomy allows the stones to be retrieved in the same setting (see Choleodochal Exploration section). If the expertise and/or the instrumentation for laparoscopic common bile duct exploration are not available, a drain should be left adjacent to the cystic duct and the patient scheduled for endoscopic sphincterectomy the following day. An open common bile duct exploration is an option if the endoscopic method has already been tried or is, for some reason, not feasible. If a choledochotomy is performed, a T tube is left in place. Stones impacted in the ampulla may be difficult for both endoscopic ductal clearance as well as common bile duct exploration (open or laparoscopic). In these cases the common bile duct is usually quite dilated (about 2 cm in diameter). A cholecdochoduodenostomy or a Roux-en-Y choledochojejunos-tomy may be the best option under this circumstance.

Retained or recurrent stones following cholecystectomy are best treated endoscopically (Fig. 32-16). If the stones were deliberately left in place at the time of surgery or diagnosed shortly after the cholecystectomy, they are classified as retained; those diagnosed months or years later are termed recurrent. If a common bile duct exploration was performed and a T tube left in place, a T-tube cholangiogram is obtained before its removal. Retained stones can be retrieved either endoscopically or via the T-tube tract once it has matured (2–4 weeks). The T tube is then removed and a catheter passed through the tract into the common bile duct. Under fluoroscopic guidance, the stones are retrieved with baskets or balloons. Recurrent stones may be multiple and large. A generous endoscopic sphincterotomy will allow stone retrieval as well as spontaneous passage of retained and recurrent stones. Patients >70 years old presenting with bile duct stones should have their ductal stones cleared endoscopically. Studies comparing surgery to endoscopic treatment have documented less morbidity and mortality for endoscopic treatment in this group of patients. They do not need to be submitted for a cholecystectomy, as only about 15% will become symptomatic from their gallbladder stones, and such patients can be treated as the need arises by a cholecystectomy.

**Cholangitis.** Cholangitis is one of the two main complications of choledochal stones, the other being gallstone pancreatitis. Acute cholangitis is an ascending bacterial infection in association with partial or complete obstruction of the bile ducts. Hepatic bile is sterile, and bile in the bile ducts is kept sterile by continuous bile flow and by the presence of antibacterial substances in bile, such as immunoglobulin. Mechanical hindrance to bile flow facilitates bacterial contamination. Positive bile cultures are common in the presence of bile duct stones as well as with other causes of obstruction. Biliary bacterial contamination alone does not lead to clinical cholangitis; the combination of both significant bacterial contamination and biliary obstruction is required for its development. Gallstones are the most common cause of obstruction in cholangitis; other causes are benign
Diagnosis and Management

Leukocytosis, hyperbilirubinemia, and elevation of alkaline phosphatase and transaminases are common and, when present, support the clinical diagnosis of cholangitis. Ultrasonography is helpful, as it will document the presence of gallbladder stones, demonstrate dilated ducts, and possibly pinpoint the site of obstruction; however, rarely will it elucidate the exact cause. The definitive diagnostic test is ERC. In cases in which ERC is not available, PTC is indicated. Both ERC and PTC will show the level and the reason for the obstruction, allow culture of the bile, possibly allow the removal of stones if present, and allow drainage of the bile ducts with drainage catheters or stents. CT scanning and MRI will show pancreatic and periampullary masses, if present, in addition to the ductal dilatation.

The initial treatment of patients with cholangitis includes IV antibiotics and fluid resuscitation. These patients may require intensive care unit monitoring and vasopressor support. Most patients will respond to these measures. However, the obstructed bile duct must be drained as soon as the patient has been stabilized. About 15% of patients will not respond to antibiotics and fluid resuscitation, and an emergency biliary decompression may be required. Biliary decompression may be accomplished endoscopically, via the percutaneous transhepatic route, or surgically. The selection of procedure should be based on the level and the nature of the biliary obstruction. Patients with choledocholithiasis or periampullary malignancies are best approached endoscopically, with sphincterotomy and stone removal, or by placement of an endoscopic biliary stent. In patients in whom the obstruction is more proximal or perihilar, or when a stricture in a biliary-enteric anastomosis is the cause or the endoscopic route has failed, percutaneous transhepatic drainage is used. When neither ERC nor PTC is available, an emergent operation for decompression of the common bile duct with a T tube may be necessary and lifesaving. Definitive operative therapy should be deferred until the cholangitis has been treated and the proper diagnosis established. Patients with indwelling stents and cholangitis usually require repeated imaging and exchange of the stent over a guidewire.

Acute cholangitis is associated with an overall mortality rate of approximately 5%. When associated with renal failure, cardiac impairment, hepatic abscesses, and malignancies, the morbidity and mortality rates are much higher.

Biliary Pancreatitis. Gallstones in the common bile duct are associated with acute pancreatitis. Obstruction of the pancreatic duct by an impacted stone or temporary obstruction by a stone passing through the ampulla may lead to pancreatitis. The exact mechanism by which the obstruction of the pancreatic duct leads to pancreatitis is still not clear. An ultrasonogram of the biliary tree in patients with pancreatitis is essential. If gallstones are present and the pancreatitis is severe, an ERC with sphincterotomy and stone extraction may abort the episode of pancreatitis. If gallstones are present and the pancreatitis is mild and self-limited, the stone has probably passed. For these patients, a cholecystectomy and an intraoperative cholangiogram or a preoperative ERC is indicated.
Cholangiohepatitis

Cholangiohepatitis, also known as recurrent pyogenic cholangitis, is endemic to the Orient. It also has been encountered in the Chinese population in the United States, as well as in Europe and Australia. It affects both sexes equally and occurs most frequently in the third and fourth decades of life. Cholangiohepatitis is caused by bacterial contamination (commonly \textit{E. coli}, \textit{Klebsiella} species, \textit{Bacteroides} species, or \textit{Enterococcus faecalis}) of the biliary tree, and often is associated with biliary parasites such as \textit{Clonorchis sinensis}, \textit{Opisthorchis viverrini}, and \textit{Ascaris lumbricoides}. Bacterial enzymes cause deconjugation of bilirubin, which precipitates as bile sludge. The sludge and dead bacterial cell bodies form brown pigment stones. The nucleus of the stone may contain an adult \textit{Clonorchis} worm, an ovum, or an ascidian. These stones are formed throughout the biliary tree and cause partial obstruction that contributes to the repeated bouts of cholangitis. Biliary strictures form as a result of recurrent cholangitis and lead to further stone formation, infection, hepatic abscesses, and liver failure (secondary biliary cirrhosis).

The patient usually presents with pain in the right upper quadrant and epigastrium, fever, and jaundice. Recurrence of symptoms is one of the most characteristic features of the disease. The episodes may vary in severity but, without intervention, will gradually lead to malnutrition and hepatic insufficiency. An ultrasound will detect stones in the biliary tree, pneumobilia from infection due to gas-forming organisms, liver abscesses, and, occasionally, strictures. The gallbladder may be thickened but is inflamed in about 20% of patients and rarely contains stones. MRCP and PTC are the mainstays of biliary imaging for cholangiohepatitis. They can detect obstructions, define strictures and stones, and allow emergent decompression of the biliary tree in the septic patient. Hepatic abscesses may be drained percutaneously. The long-term goal of therapy is to extract stones and debris and relieve strictures. It may take several procedures and require a Roux-en-Y hepaticojejunostomy to establish biliary-enteric continuity. Occasionally, resection of involved areas of the liver may offer the best form of treatment. Recurrences are common and the prognosis is poor once hepatic insufficiency has developed.

**OPERATIVE INTERVENTIONS FOR GALLSTONE DISEASE**

**Cholecystostomy**

A cholecystostomy decompresses and drains the distended, inflamed, hydropic, or purulent gallbladder. It is applicable if the patient is not fit to tolerate an abdominal operation. Ultrasound-guided percutaneous drainage with a pigtail catheter is the procedure of choice. The catheter is inserted over a guidewire that has been passed through the abdominal wall, the right lobe of the liver, and into the gallbladder. The catheter is inserted over the guidewire that has been passed through the abdominal wall, the right lobe of the liver, and into the gallbladder (Fig. 32-17). By passing the catheter through the liver, the risk of bile leak around the catheter is minimized. The catheter can be removed when the inflammation has resolved and the patient’s condition improved. The gallbladder can be removed later, if indicated, usually by laparoscopy. Surgical cholecystostomy with a large catheter placed under local anesthesia is rarely required today.

**Cholecystectomy**

Cholecystectomy is the most common major abdominal procedure performed in Western countries. Carl Langenbuch performed the first successful cholecystectomy in 1882, and for >100 years, it was the standard treatment for symptomatic gallbladder stones. Open cholecystectomy was a safe and effective treatment for both acute and chronic cholecystitis. In 1987, laparoscopic cholecystectomy was introduced by Philippe Mouret in France and quickly revolutionized the treatment of gallstones. It not only supplanted open cholecystectomy, but also more or less ended attempts for noninvasive management of gallstones, such as extracorporeal shock wave and bile salt therapy. Laparoscopic cholecystectomy offers a cure for gallstones with a minimally invasive procedure, minor pain and scarring, and early return to full activity. Today, laparoscopic cholecystectomy is the treatment of choice for symptomatic gallstones.

Absolute contraindications for the procedure are uncontrolled coagulopathy and end-stage liver disease. In the latter instance, liver transplantation, with cholecystectomy, may be used for treatment of severe recurrent gallstone disease. Rarely, patients with severe obstructive pulmonary disease or congestive heart failure (e.g., cardiac ejection fraction <20%) may not tolerate pneumoperitoneum with carbon dioxide and require open cholecystectomy. Conditions formerly believed to be relative contraindications such as acute cholecystitis, gangrene and empyema of the gallbladder, biliary-enteric fistulae, obesity, pregnancy, ventriculoperitoneal shunt, cirrhosis, and previous upper abdominal procedures are now considered risk factors for a potentially difficult laparoscopic cholecystectomy. When important anatomic structures cannot be clearly identified or when no progress is made over a set period of time, a conversion to an open procedure is usually indicated. In the elective setting, conversion to an open procedure is needed in about 5% of patients. Emergent procedures may require more skill on the part of the surgeon and be needed in patients with complicated gallstone disease; the incidence of conversion is 10% to 30%. Conversion to an open procedure is not a failure, and the possibility should be discussed with the patient preoperatively.

Serious complications are rare. The mortality rate for laparoscopic cholecystectomy is about 0.1%. Wound infection and cardiopulmonary complication rates are considerably lower following laparoscopic cholecystectomy than are those for an open procedure. However, laparoscopic cholecystectomy is associated with a higher injury rate to the bile ducts (see later section, Injury to the Biliary Tract).
Patients undergoing cholecystectomy should have a complete blood count and liver function tests preoperatively. Prophylaxis against deep venous thrombosis with either low molecular weight heparin or compression stockings is indicated. The patient should be instructed to empty their bladder before coming to the operating room. Urinary catheters are rarely needed. An orogastric tube is placed if the stomach is distended with gas and is removed at the end of the operation.

**Laparoscopic Cholecystectomy.** The patient is placed supine on the operating table with the surgeon standing at the patient’s left side. Some surgeons prefer to stand between the patient’s legs while doing laparoscopic procedures in the upper abdomen. The pneumoperitoneum is created with carbon dioxide gas, either with an open technique or by closed needle technique. Initially, a small incision is made in the upper edge of the umbilicus. With the closed technique, a special hollow insufflation needle (Veress needle) that is spring-loaded with a retractable cutting outer sheath is inserted into the peritoneal cavity and used for insufflation. Once an adequate pneumoperitoneum is established, a 10-mm trocar is inserted through the supraumbilical incision. With the open technique, the supraumbilical incision is carried through the fascia and into the peritoneal cavity. A special blunt cannula (Hasson cannula) is inserted into the peritoneal cavity and anchored to the fascia. The laparoscope with the attached video camera is passed through the umbilical port and the abdomen inspected. Three additional ports are placed under direct vision (Fig. 32-18). A 10-mm port is placed in the epigastrium, a 5-mm port in the middle of the clavicular line, and a 5-mm port in the right flank, in line with the gallbladder fundus. Occasionally, a fifth port is required for better visualization in patients recovering from pancreatitis or those with semi-acute cholecystitis, as well as in very obese patients.

Through the lateral-most port, a grasper is used to grasp the gallbladder fundus. It is retracted over the liver edge upward and toward the patient’s right shoulder to expose the proximal gallbladder and the hilar area. Exposure of the hilar area may be facilitated by placing the patient in reverse Trendelenburg position with slight tilting of the table to bring the right side up. Through the midclavicular port a second grasper is used to grasp the gallbladder infundibulum and retract it laterally to expose the triangle of Calot. Before this, it may be necessary to take down any adhesions between the omentum, duodenum, or colon, and the gallbladder. Most of the dissection is carried out through the epigastric port using a dissector, hook cautery, or scissors.

The dissection starts at the junction of the gallbladder and the cystic duct. A helpful anatomic landmark is the cystic artery lymph node. The peritoneum, fat, and loose areolar tissue around the gallbladder and the cystic duct–gallbladder junction is dissected off toward the bile duct. This is continued until the gallbladder neck and the proximal cystic duct are clearly identified. The next step is the identification of the cystic artery, which usually runs parallel to and somewhat behind the cystic duct. A hemoclip is placed on the proximal cystic duct, followed by cutting through the cystic duct wall. If an intraoperative cholangiogram is to be performed, a small incision is made on the anterior surface of the cystic duct, just proximal to the clip, and a cholangiogram catheter is passed into the cystic duct. Once the cholangiogram is completed, the catheter is removed and two clips are placed proximal to the incision, and the cystic duct is divided. A wide cystic duct may be too big for clips, requiring the placement of a pre-tied loop ligature to close. The cystic artery is then clipped and divided.

Finally, the gallbladder is dissected out of the gallbladder fossa, using either a hook or scissors with electrocautery. Before the gallbladder is removed from the liver edge, the operative field is carefully searched for bleeding points, and the placement of the clips on the cystic duct and cystic artery is inspected. The gallbladder is removed through the umbilical incision. The fascial defect and skin incision may need to be enlarged if the stones are large. If the gallbladder is acutely inflamed or gangrenous, or if the gallbladder is perforated, it is placed in a retrieval bag before it is removed from the abdomen. Any bile or blood that has accumulated during the procedure is sucked away, and if stones were spilled, they are retrieved, placed inside a retrieval bag, and removed. If the gallbladder was severely inflamed or gangrenous or if any bile or blood is expected to accumulate, a closed-suction drain can be placed through one of the 5-mm ports and left underneath the right liver lobe close to the gallbladder fossa.

**Open Cholecystectomy.** The same surgical principles apply for laparoscopic and open cholecystectomies. Open cholecystectomy has become an uncommon procedure, usually performed either as a conversion from laparoscopic cholecystectomy or as a second procedure in patients who require laparotomy for another reason. After the cystic artery and cystic duct have been identified, the gallbladder is dissected free from the liver bed, starting at the fundus. The dissection is carried proximally toward the cystic artery and the cystic duct, which are then ligated and divided.

**Intraoperative Cholangiogram or Ultrasound.** The bile ducts are visualized under fluoroscopy by injecting contrast through a catheter placed in the cystic duct (Fig. 32-19A). Their size can then be evaluated, the presence or absence of common bile duct stones assessed, and filling defects confirmed, as the dye passes into the duodenum. Routine intraoperative cholangiography will detect stones in approximately 7% of patients, as well as outlining the anatomy and detecting injury. Laparoscopic ultrasonography is as accurate as intraoperative cholangiography in detecting common bile duct stones, and it is less invasive; however, it requires more skill to perform and interpret.

**Common Bile Duct Exploration**

Common bile duct stones that are detected intraoperatively on intraoperative cholangiography or ultrasound may be managed with laparoscopic choledochal exploration as a part of the laparoscopic cholecystectomy procedure. Patients with common bile duct stones detected preoperatively, but in whom endoscopic clearance was either not available or unsuccessful, should also have their ductal stones managed during the cholecystectomy.

If the stones in the duct are small, they may sometimes be flushed into the duodenum with saline irrigation via the cholangiography catheter after the sphincter of Oddi has been relaxed with glucagon. If irrigation is unsuccessful, a balloon catheter may be passed via the cystic duct and down the common bile duct, where it is inflated and withdrawn to retrieve the stones. The next attempt is usually made with a wire basket passed...
under fluoroscopic guidance to catch the stones (Fig. 32.20). If needed, a flexible choledochoscope is the next step. The cystic duct may have to be dilated to allow its passage. Once in the common bile duct, the stones may be caught into a wire basket under direct vision or pushed into the duodenum. When the duct has been cleared, the cystic duct is ligated and cut and the cholecystectomy completed. Occasionally, a choledochotomy, an incision into the common bile duct itself, is necessary. The flexible choledochoscope is then passed into the duct for visualization and clearance of stones. The choledochotomy is sutured.
with a T tube left in the common bile duct with one end taken out through the abdominal wall for decompression of the bile ducts. By managing common bile duct stones at the time of the cholecystectomy, the patients can have all of their gallstone disease treated with one invasive procedure. It does, however, depend on the available surgical expertise.

**Common Bile Duct Drainage Procedures**

Rarely, when the stones cannot be cleared and/or when the duct is very dilated (>1.5 cm in diameter), a choledochal drainage procedure is performed (Fig. 32-21). Choledochoduodenostomy is performed by mobilizing the second part of the duodenum (a Kocher maneuver) and anastomosing it side to side with the common bile duct.

A choledochojejunostomy is done by bringing up a 45-cm Roux-en-Y limb of jejunum and anastomosing it end to side with the common bile duct.

Choledochojejunostomy or, more often, a hepaticojejunostomy, also can be used to repair common bile duct strictures or as a palliative procedure for malignant obstruction in the periampullary region. If the common bile duct has been transected or injured, it can be managed by an end-to-end choledochojejunostomy.

**Transduodenal Sphincterotomy**

In the majority of cases, endoscopic sphincterotomy has replaced open transduodenal sphincterotomy. If an open procedure for common bile duct stones is being done in which the stones are impacted, recurrent, or multiple, the transduodenal approach may be feasible. The duodenum is incised transversely. The sphincter then is incised at the 11 o’clock position to avoid injury to the pancreatic duct. The impacted stones are removed, as are large stones from the duct. There is no need to fully clear the duct of stones, as they can pass spontaneously through the cut sphincter.

**OTHER BENIGN DISEASES AND LESIONS**

**Acalculous Cholecystitis**

Acute inflammation of the gallbladder can occur without gallstones. Acalculous cholecystitis typically develops in critically ill patients in the intensive care unit. Patients on parenteral nutrition with extensive burns, sepsis, major operations, multiple trauma, or prolonged illness with multiple organ system failure are at risk for developing acalculous cholecystitis. The cause is unknown, but gallbladder distention with bile stasis and ischemia has been implicated as causative factors. Pathologic examination of the gallbladder wall reveals edema of the serosa and muscular layers, with patchy thrombosis of arterioles and venules.

The symptoms and signs depend on the condition of the patient, but in the alert patient, they are similar to acute calculus cholecystitis, with right upper quadrant pain and tenderness, fever, and leukocytosis. In the sedated or unconscious patient, the clinical features are often masked, but fever and elevated WBC count, as well as elevation of alkaline phosphatase and bilirubin, are indications for further investigation.

Ultrasonography is usually the diagnostic test of choice, as it can be done bedside in the intensive care unit. It can demonstrate the distended gallbladder with thickened wall, biliary sludge, pericholecystic fluid, and the presence or absence of abscess formation. Abdominal CT scan can aid in the diagnosis of acalculous cholecystitis and additionally allows imaging of the abdominal cavity and chest to rule out other sources of infection. A HIDA scan can be useful and will show nonvisualization of...
Figure 32-20. Laparoscopic bile duct exploration. I. Transcystic basket retrieval using fluoroscopy. A. The basket has been advanced past the stone and opened. B. The stone has been entrapped in the basket, and together, they are removed from the cystic duct. II. Transcystic choledochoscopy and stone removal. C. The basket has been passed through the working channel of the scope, and the stone is entrapped under direct vision. D. Entrapped stone. E. A view from the choledochoscope. III. Choledochotomy and stone removal. F. A small incision is made in the common bile duct. G. The common bile duct is cleared of stones. H. Figure 32-21. Biliary enteric anastomoses. There are three types. I. Choledochoduodenostomy. A. The distal common bile duct is opened longitudinally, as is the duodenum. B. Interrupted sutures are placed between the common bile duct and the duodenum. C. Completed choledochoduodenostomy. II. Choledochojejunostomy. D. The common bile duct and small bowel are divided. E. A Roux-en-Y limb of jejunum is anastomosed to the choledochus. III. Hepaticojejunostomy. F. The entire extrahepatic biliary tree has been resected and the reconstruction done with a Roux-en-Y limb of jejunum. G. Percutaneous transhepatic stents are placed across hepaticojejunostomy.
the gallbladder, but it is a less sensitive test with high false-positive
rates in patients who are fasting, on total parenteral nutrition,
or have liver disease.\textsuperscript{63} Acalculous cholecystitis requires urgent
intervention. Percutaneous ultrasound- or CT-guided cholecys-
tostomy is the treatment of choice for these patients, as they
are usually unfit for surgery (see Fig. 32-17). If the diagnosis
is uncertain, percutaneous cholecystostomy is both diagnostic
and therapeutic. About 90\% of patients will improve with the
percutaneous cholecystostomy. However, if they do not improve,
other steps, such as open cholecystostomy or cholecystectomy,
may be required. If needed, cholecystectomy is performed after
the patient has recovered from the underlying disease.

Biliary Cysts

Choledochal cysts are congenital cystic dilatations of the extra-
hepatic and/or intrahepatic biliary tree. They are rare—the
incidence is between 1:100,000 and 1:150,000 in populations
of Western countries—but are more commonly seen in popu-
lations of Eastern countries. Choledochal cysts affect females
three to eight times more often than males. Although frequently
diagnosed in infancy or childhood, as many as one half of the
patients have reached adulthood when diagnosed. The cause is
unknown. Weakness of the bile duct wall and increased pressure
secondary to partial biliary obstruction are required for biliary
cyst formation. More than 90\% of patients have an anomalous
pancreaticobiliary duct junction, with the pancreatic duct join-
ing the common bile duct >1 cm proximal to the ampulla. This
results in a long common channel that may allow reflux of
pancreatic secretions into the biliary tract, leading to inflam-
matory changes, increased biliary pressure, and cyst formation.

Choledochal cysts are classified into five types (Fig. 32-22).
The cysts are lined with cuboidal epithelium and can vary in size
from 2 cm in diameter to giant cysts.

Adults commonly present with jaundice or cholangitis. Less
than one half of patients present with the classic clinical
triad of abdominal pain, jaundice, and a mass. Ultrasonography
or CT scanning will confirm the diagnosis, but endoscopic chol-
angiography, transhepatic cholangiography, or MRC is required
to assess the biliary anatomy and to plan the appropriate surgical
treatment. For types I, II, and IV, excision of the extrahe-
patic biliary tree, including cholecystectomy, with a Roux-en-Y
hepaticojejunostomy is ideal. In type IV, additional segmental
resection of the liver may be appropriate, particularly if intra-
hepatic stones, strictures, or abscesses are present or if the dilata-
tions are confined to one lobe. The risk of cholangiocarcinoma
developing in choledochal cysts is as high as 15\% in adults and
supports complete excision when they are diagnosed. For type
III, sphincterotomy is recommended.\textsuperscript{64}

![Figure 32-22. Classification of choledochal cysts. Type I, fusiform or cystic dilations of the extrahepatic biliary tree, is the most common
type, making up >50\% of the choledochal cysts. Type II, saccular diverticulum of an extrahepatic bile duct. Rare, <5\% of choledochal cysts.
Type III, bile duct dilation within the duodenal wall (choledochoceles), makes up about 5\% of choledochal cysts. Types IVa and IVb, mul-
tiple cysts, make up 5\% to 10\% of choledochal cysts. Type IVa affects both extrahepatic and intrahepatic bile ducts, whereas type IVb cysts
affect the extrahepatic bile ducts only. Type V, intrahepatic biliary cysts, is very rare and makes up 1\% of choledochal cysts.](image)
Sclerosing Cholangitis
Sclerosing cholangitis is an uncommon disease characterized by inflammatory strictures involving the intrahepatic and extrahepatic biliary tree. It is a progressive disease that eventually results in secondary biliary cirrhosis. Sometimes, biliary strictures are clearly secondary to biliary stones, acute cholangitis, previous biliary surgery, or toxic agents, and are termed secondary sclerosing cholangitis. However, primary sclerosing cholangitis is a disease entity of its own, with no known attributing cause. It is associated with ulcerative colitis in about two thirds of patients. Other diseases associated with sclerosing cholangitis include Riedel’s thyroiditis and retroperitoneal fibrosis. Autoimmune reaction, chronic low-grade bacterial or viral infection, toxic reaction, and genetic factors have all been suggested to play a role in its pathogenesis. The human leukocyte antigen haplotypes HLA-B8, -DR3, -DQ2, and -DRw52A, commonly found in patients with autoimmune diseases, also are more frequently seen in patients with sclerosing cholangitis than in controls. Patients with sclerosing cholangitis are at risk for developing cholangiocarcinoma. Eventually, 10% to 20% of the patients will develop cancer. Cholangiocarcinoma can present at any time during the disease process and does not correlate with the extent of sclerosing cholangitis or the development of liver failure, but frequently follows an aggressive course.

The mean age of presentation is 30 to 45 years, and men are affected twice as commonly as women. The usual presentation is intermittent jaundice, fatigue, weight loss, pruritus, and abdominal pain. Symptoms of acute cholangitis are rare, without preceding biliary tract intervention or surgery. More than one half of patients are asymptomatic when diagnosed. In several patients with ulcerative colitis, abnormal liver function tests found on routine testing lead to the diagnosis. The clinical course in sclerosing cholangitis is highly variable, but cyclic remissions and exacerbations are typical. However, some patients remain asymptomatic for years, while others progress rapidly with the oblitative inflammatory changes leading to secondary biliary cirrhosis and liver failure. In patients with associated ulcerative colitis, the course of each disease seems independent of the other. Colectomy for the colitis makes no difference to the course of primary sclerosing cholangitis. The median survival for patients with primary sclerosing cholangitis from the time of diagnosis ranges from 10 to 12 years, and most die from hepatic failure.65

The clinical presentation and elevation of alkaline phosphatase and bilirubin may suggest the diagnosis, but ERC, revealing multiple dilatations and strictures (beading) of both the intra- and extrahepatic biliary tree, confirms it. The hepatic duct bifurcation is often the most severely affected segment. A liver biopsy may not be diagnostic, but is important to determine the degree of hepatic fibrosis and the presence of cirrhosis. Sclerosing cholangitis is followed by ERC and liver biopsies to provide appropriate management.

There is no known effective medical therapy for primary sclerosing cholangitis and no known curative treatment. Corticosteroids, immunosuppressants, ursodeoxycholic acid, and antibiotics have been disappointing. Biliary strictures can be dilated and stented either endoscopically or percutaneously. These measures have given short-term improvements in symptoms and serum bilirubin levels and long-term improvements in only less than one half of the patients. Surgical management with resection of the extrahepatic biliary tree and hepaticojejunostomy has produced reasonable results in patients with extrahepatic and bifurcation strictures, but without cirrhosis or significant hepatic fibrosis.66 In patients with sclerosing cholangitis and advanced liver disease, liver transplantation is the only option. It offers excellent results, with overall 5-year survival as high as 85%. Primary sclerosing cholangitis recurs in 10% to 20% of patients and may require retransplantation.67,68

Stenosis of the Sphincter of Oddi
A benign stenosis of the outlet of the common bile duct is usually associated with inflammation, fibrosis, or muscular hypertrophy. The pathogenesis is unclear, but trauma from the passage of stones, sphincter motility disorders, and congenital anomalies have been suggested. Episodic pain of the biliary type with abnormal liver function tests is a common presentation. However, recurrent jaundice or pancreatitis also may play a role. A dilated common bile duct that is difficult to cannulate with delayed emptying of the contrast are useful diagnostic features. Ampullary manometry and special provocation tests are available in specialized units. If the diagnosis is well established, endoscopic or operative sphincterotomy will yield good results.69

Bile Duct Strictures
Benign bile duct strictures can have numerous causes. However, the vast majority were caused by operative injury, most commonly by laparoscopic cholecystectomy (see later section, Injury to the Biliary Tract). Other causes include fibrosis due to chronic pancreatitis, common bile duct stones, acute cholangitis, biliary obstruction due to cholecystolithiasis (Mirizzi’s syndrome), sclerosing cholangitis, cholangiohepatitis, and strictures of a biliary-enteric anastomosis. Bile duct strictures that go unrecognized or are improperly managed may lead to recurrent cholangitis, secondary biliary cirrhosis, and portal hypertension.70

Patients with bile duct strictures most commonly present with episodes of cholangitis. Less commonly, they may present with jaundice without evidence of infection. Liver function tests usually show evidence of cholestasis. An ultrasound or a CT scan will show dilated bile ducts proximal to the stricture, as well as provide some information about the level of the stenosis. MRC will also provide good anatomic information about the location and the degree of dilatation. In patients with intrahepatic ductal dilatation, a percutaneous transhepatic cholangiogram will outline the proximal biliary tree, define the stricture and its location, and allow decompression of the biliary tree with transhepatic catheters or stents (Fig. 32-23). An endoscopic cholangiogram will outline the distal bile duct. Treatment depends on the location and the cause of the stricture. Percutaneous or endoscopic dilatation and/or stent placement give good results in more than one half of patients. Surgery with Roux-en-Y choledochojejunostomy or hepaticojejunostomy is the standard of care with good or excellent results in 80% to 90% of patients.71 Choledochoduodenostomy may be a choice for strictures in the distal-most part of the common bile duct.

Gallbladder
Injuries to the gallbladder are uncommon. Penetrating injuries are usually caused by gunshot wounds or stab wounds, and rarely by a needle biopsy procedure of the liver. Nonpenetrating trauma is extremely rare. These types of injury to the gallbladder include contusion, avulsion, laceration, rupture, and

INJURY TO THE BILIARY TRACT

Gallbladder
Injuries to the gallbladder are uncommon. Penetrating injuries are usually caused by gunshot wounds or stab wounds, and rarely by a needle biopsy procedure of the liver. Nonpenetrating trauma is extremely rare. These types of injury to the gallbladder include contusion, avulsion, laceration, rupture, and...
Less commonly, biliary injury is associated with acute or chronic inflammation, obesity, anatomic variations, and injury during laparoscopic cholecystectomy. These include iatrogenic, occurring in the course of laparoscopic or open cholecystectomy, and entered the common hepatic duct during gastrectomy, and dissection of the hepatic ducts. A number of intraoperative technical factors have been implicated in biliary injuries. Excessive cephalad retraction of the gallbladder may cause injury to intrahepatic ducts, and poor clip placement close to the hilar area or to structures not well visualized can result in a clip across a bile duct.

The routine use of intraoperative fluoroscopic cholangiography to prevent bile duct injury is controversial. Routine use may limit the extent of injury but does not seem to prevent it entirely. Nonetheless, the frequency of bile duct injuries is cut by 50% when an intraoperative cholangiogram is performed. Critical to the successful use of cholangiography is accurate interpretation of the imaging. It is important to check that the whole biliary system fills with contrast, including both major ducts on the right and the left hepatic duct, and there is no extravasation of contrast.

**Diagnosis.** Only about 25% of major bile duct injuries (common bile duct or hepatic duct) are recognized at the time of operation. Most commonly, intraoperative bile leakage, recognition of the correct anatomy, and an abnormal cholangiogram lead to the diagnosis of a bile duct injury. More than half of patients with biliary injury will present within the first postoperative month. The remainder will present months or years later, with recurrent cholangitis or cirrhosis from a remote bile duct injury. In the early postoperative period, patients present either with progressive elevation of liver function tests due to an occluded or a stenosed bile duct, or with a bile leak from an injured duct. Bile leak, most commonly from the cystic duct stump, a transected aberrant right hepatic duct, or a lateral injury to the main bile duct, usually presents with pain, fever, and a mild elevation of liver function tests. A CT scan or an ultrasound will show a collection (biloma) in the gallbladder area or free fluid (bile) in the peritoneum (Fig. 32-24). Bilious drainage through a placed drain or a percutaneously placed catheter, injection of water-soluble contrast media through the drainage tract (sinogram) can often define the site of leakage and the anatomy of the biliary tree.

CT scan and ultrasound also are important in the initial evaluation of the jaundiced patient, as they can demonstrate the dilated part of the biliary tree proximal to the stenosis or obstruction, and may identify the level of the extrahepatic bile duct obstruction. In the jaundiced patient with dilated intrahepatic ducts, a percutaneous cholangiogram will outline the anatomy and the proximal extent of the injury and allow decompression of the biliary tree with catheter or stent placements. An endoscopic cholangiogram demonstrates the anatomy distal to the injury and may allow the placement of stents across a stricture to

**Figure 32-23.** An endoscopic retrograde cholangiography showing stricture of the common hepatic duct (arrow). The patient had recently had a laparoscopic cholecystectomy; clips from the operation can be seen projected over the common bile duct.

A number of different factors are associated with bile duct injury during laparoscopic cholecystectomy. These include acute or chronic inflammation, obesity, anatomic variations, and bleeding. Surgical technique with inadequate exposure and failure to identify structures before ligating or dividing them are the most common cause of significant biliary injury. The bile ducts may be narrow and can be mistaken for the cystic duct. The cystic duct may run along side the common bile duct before joining it, leading the surgeon to the wrong place. Additionally, the cystic duct may enter the right hepatic duct, and the right hepatic duct may run aberrantly, coursing through the triangle of Calot and entering the common hepatic duct. A number of intraoperative technical factors have been implicated in biliary injuries. Excessive cephalad retraction of the gallbladder may cause injury to intrahepatic ducts, and poor clip placement close to the hilar area or to structures not well visualized can result in a clip across a bile duct.
relieve an obstruction (see Fig. 32-23). MRI cholangiography, if available, provides an excellent, noninvasive delineation of the biliary anatomy both proximal and distal to the injury.

**Management.** The management of bile duct injuries depends on the type, extent, and level of injury, and the time of its diagnosis. Initial proper treatment of bile duct injury diagnosed during the cholecystectomy can avoid the development of a bile duct stricture. If a major injury is discovered and an experienced biliary surgeon is not available, an external drain and, if necessary, transhepatic biliary catheters are placed, and the patient is transferred to a referral center. If the injured duct is <3 mm or those draining a single hepatic segment can safely be ligated. If the injured duct is ≥4 mm, it is likely to drain multiple segments or an entire lobe, and thus needs to be reimplanted. Lateral injury to the common bile duct or the common hepatic duct, recognized at the time of surgery, is best managed with a T-tube placement. If the injury is a small incision in the duct, the T tube may be placed through it as if it were a formal choledochotomy. In more extensive lateral injuries, the T tube should be placed through a separate choledochotomy and the injury closed over the T-tube end to minimize the risk of subsequent stricture formation.

Major bile duct injuries such as transection of the common hepatic or common bile duct are best managed at the time of injury. In many of these major injuries, the bile duct has not only been transected, but a variable length of the duct removed. This injury usually requires a biliary enteric anastomosis with a jejunal loop. Either an end-to-side Roux-en-Y choledochojejunostomy or, more commonly, a Roux-en-Y hepaticojejunostomy should be performed. Transhepatic biliary catheters are placed through the anastomosis to stent it and to provide access to the biliary tract for drainage and imaging. Although rare, when the injury is to the distal common bile duct, a choledochochoduodenostomy can be performed. If there is no or minimal loss of ductal length, a duct-to-duct repair may be done over a T tube that is placed through a separate incision. It is critical to perform a tension-free anastomosis to minimize the high risk of postoperative stricture formation.

Cystic duct leaks can usually be managed with percutaneous drainage of intra-abdominal fluid collections followed by an endoscopic biliary stenting (see Fig. 32-24).

Major injuries diagnosed postoperatively require transhepatic biliary catheter placement for biliary decompression as well as percutaneous drainage of intra-abdominal bile collections, if any. When the acute inflammation has resolved 6 to 8 weeks later, operative repair is performed.

Patients with bile duct stricture from an injury or as a sequela of previous repair usually present with either progressive elevation of liver function tests or cholangitis. The initial management usually includes transhepatic biliary catheter placement for decompression as well as for defining the anatomy and the location and the extent of the damage. These catheters will also serve as useful technical aids during subsequent biliary enteric anastomosis. An anastomosis is performed between the duct proximal to the injury and a Roux loop of jejunum. Balloon dilation of a stricture usually requires multiple attempts and rarely provides adequate long-term relief. Self-expanding metal or plastic stents, placed either percutaneously or endoscopically across the stricture, can provide temporary drainage and, in the high-risk patient, permanent drainage of the biliary tree.

**Outcome.** Good results can be expected in 70% to 90% of patients with bile duct injuries. The best results are obtained when the injury is recognized during the cholecystectomy and repaired by an experienced biliary tract surgeon. The operative mortality rate varies from 0% to almost 30% in various series, but commonly is about 5% to 8%. Common complications that are specific for bile duct repairs include cholangitis, external biliary fistula, bile leak, subhepatic and subphrenic abscesses, and hemobilia. Restenosis of a biliary enteric anastomosis occurs in about 10% of patients, and may manifest up to 20 years after the initial procedure. Approximately two thirds of recurrent strictures become symptomatic within 2 years after repair. The more proximal strictures are associated with a lower success rate than are distal ones. The worst results are in patients with many operative revisions and in those who have evidence of
liver failure and portal hypertension. However, previous repair does not preclude successful outcome of repeated attempts, particularly in patients with good liver function. Patients with deteriorating liver function are candidates for liver transplants.

TUMORS

Carcinoma of the Gallbladder
Cancer of the gallbladder is a rare malignancy that occurs predominantly in the elderly. It is an aggressive tumor, with poor prognosis except when incidentally diagnosed at an early stage after cholecystectomy for cholelithiasis. The overall reported 5-year survival rate is about 5%.79

Incidence. Gallbladder cancer is the fifth most common GI malignancy in Western countries. However, it accounts for only 2% to 4% of all malignant GI tumors, with about 5000 new cases diagnosed annually in the United States. It is two to three times more common in females than males, and the peak incidence is in the seventh decade of life. Its occurrence in random autopsy series is about 0.4%, but approximately 1% of patients undergoing cholecystectomy for gallstone disease are found incidentally to have gallbladder cancer. The incidence of gallbladder cancer is particularly high in native populations of the United States, Mexico, and Chile. The annual incidence in Native American females with gallstones approaches 75 per 100,000, compared with the overall incidence of gallbladder cancer of 2.5 cases per 100,000 residents in the United States.80

Etiology. Cholelithiasis is the most important risk factor for gallbladder carcinoma, and up to 95% of patients with carcinoma of the gallbladder have gallstones.81 However, the 20-year risk of developing cancer for patients with gallstones is <0.5% for the overall population and 1.5% for high-risk groups. The pathogenesis has not been defined but is probably related to chronic inflammation. Larger stones (>3 cm) are associated with a 10-fold increased risk of cancer.82 The risk of developing cancer of the gallbladder is higher in patients with asymptomatic than symptomatic gallstones.

Polyoid lesions of the gallbladder are associated with increased risk of cancer, particularly in polyps >10 mm.83 The calcified “porcelain” gallbladder is associated with >20% incidence of gallbladder carcinoma. These gallbladders should be removed, even if the patients are asymptomatic. Patients with choledochal cysts have an increased risk of developing cancer anywhere in the biliary tree, but the incidence is highest in the gallbladder. Sclerosing cholangitis, anomalous pancreatico-biliary duct junction, and exposure to carcinogens (azotoluene, nitrosamines) also are associated with cancer of the gallbladder.

Pathology. Between 80% and 90% of the gallbladder tumors are adenocarcinomas. Squamous cell, adenosquamous, oat cell, and other anaplastic lesions occur rarely. The histologic subtypes of gallbladder adenocarcinomas include papillary, nodular, and tubular. Less than 10% are of the papillary type, but these are associated with an overall better outcome, as they are most commonly diagnosed while localized to the gallbladder. Cancer of the gallbladder spreads through the lymphatics, with venous drainage, and with direct invasion into the liver parenchyma. Lymphatic flow from the gallbladder drains first to the cystic duct node (Calot’s), then the pericholedochal and hilar nodes, and finally the peripancreatic, duodenal, periportal, celiac, and superior mesenteric artery nodes. The gallbladder veins drain directly into the adjacent liver, usually segments IV and V, where tumor invasion is common (Fig. 32-25). The gallbladder wall differs histologically from the intestines in that it lacks a muscularis mucosa and submucosa. Lymphatics are present in the subserosal layer only. Therefore, cancers invading but not growing through the muscular layer have minimal risk of nodal disease. When diagnosed, about 25% of gallbladder cancers are localized to the gallbladder wall, 35% have regional nodal involvement and/or extension into adjacent liver, and approximately 40% have distant metastasis.84

Clinical Manifestations and Diagnosis. Signs and symptoms of carcinoma of the gallbladder are generally indistinguishable from those associated with cholecystitis and cholelithiasis. These include abdominal discomfort, right upper quadrant pain, nausea, and vomiting. Jaundice, weight loss, anorexia, ascites, and abdominal mass are less common presenting symptoms. More than one half of gallbladder cancers are not diagnosed before surgery. Common misdiagnoses include chronic cholecystitis, acute cholecystitis, choledocholithiasis, hydrops of the gallbladder, and pancreatic cancer. Laboratory findings are not diagnostic but, if abnormal, are most often consistent with biliary obstruction. Ultrasonography often reveals a thickened, irregular gallbladder wall or a mass replacing the gallbladder. Ultrasonography may visualize tumor invasion of the liver, lymphadenopathy, and a dilated biliary tree. The sensitivity of ultrasonography in detecting gallbladder cancer ranges from 70% to 100%. A CT scan is an important tool for staging and may identify a gallbladder mass or local invasion into adjacent organs. In addition, a spiral CT scan can demonstrate vascular invasion; however, CT scan is a poor method for identifying nodal spread. In jaundiced patients, a percutaneous transhepatic or endoscopic cholangiogram may be helpful to delineate the extent of biliary tree involvement, and typically shows a long stricture of the common bile duct. With newer MRI techniques,
logic diagnosis. A CT scan or ultrasound-guided biopsy of the tumor can be obtained to provide a pathologic diagnosis.

**Treatment.** Surgery remains the only curative option for gallbladder cancer as well as for cholangiocarcinoma. However, palliative procedures for patients with unresectable cancer and jaundice or duodenal obstruction remain the most frequently performed surgery for gallbladder cancers. Today, patients with obstructive jaundice can frequently be managed with either endoscopic or percutaneously placed biliary stents. There are no proven effective options for adjuvant radiation or chemotherapy for patients with gallbladder cancer.

The pathologic stage of gallbladder cancer determines the operative treatment for patients with localized gallbladder cancer. Patients without evidence of distant metastasis warrant exploration for tissue diagnosis, pathologic staging, and possible curative resection.

Tumors limited to the muscular layer of the gallbladder (T1) are usually identified incidentally, after cholecystectomy for gallstone disease. There is near universal agreement that simple cholecystectomy is an adequate treatment for T1 lesions and results in a near 100% overall 5-year survival rate. When the tumor invades the perimuscular connective tissue without extension beyond the serosa or into the liver (T2 tumors), an extended cholecystectomy should be performed. That includes resection of liver segments IVB and V, and lymphadenectomy of the cystic duct and pericholedochal, portal, right celiac, and posterior pancreaticoduodenal lymph nodes. One half of patients with T2 tumors are found to have nodal disease on pathologic examination. Therefore, regional lymphadenectomy is an important part of surgery for T2 cancers. For tumors that grow beyond the serosa or invade the liver or other organs (T3 and T4 tumors), there is a high likelihood of intraperitoneal and distant spread. If no peritoneal or nodal involvement is found, complete tumor excision with an extended right hepatectomy (segments IV, V, VI, VII, and VIII) must be performed for adequate tumor clearance. An aggressive approach in patients who will tolerate surgery has resulted in an increased survival for T3 and T4 lesions.

**Prognosis.** Most patients with gallbladder cancer have unresectable disease at the time of diagnosis. The 5-year survival rate of all patients with gallbladder cancer is <5%, with a median survival of 6 months. Patients with T1 disease treated with cholecystectomy have an excellent prognosis (85%–100% 5-year survival rate). The 5-year survival rate for T2 lesions treated with an extended cholecystectomy and lymphadenectomy compared with simple cholecystectomy is >70% vs. 25% to 40%, respectively. Patients with advanced but resectable gallbladder cancer are reported to have 5-year survival rates of 20% to 50%. However, the median survival for patients with distant metastasis at the time of presentation is only 1 to 3 months.

Recurrence after resection of gallbladder cancer occurs most commonly in the liver or the celiac or retropancreatic nodes. The prognosis for recurrent disease is very poor. Death occurs most commonly secondary to biliary sepsis or liver failure. The main goal of follow-up is to provide palliative care. The most common problems are pruritus and cholangitis associated with obstructive jaundice, bowel obstruction secondary to carcinomatosis, and pain.

**Bile Duct Carcinoma**

Cholangiocarcinoma is a rare tumor arising from the biliary epithelium and may occur anywhere along the biliary tree. About two thirds are located at the hepatic duct bifurcation. Surgical resection offers the only chance for cure; however, many patients have advanced disease at the time of diagnosis. Therefore, palliative procedures aimed to provide biliary drainage to prevent liver failure and cholangitis are often the only therapeutic possibilities. Most patients with unresectable disease die within 1 year of diagnosis.

**Incidence.** The autopsy incidence of bile duct carcinoma is about 0.3%. The overall incidence of cholangiocarcinoma in the United States is about 1.0 per 100,000 people per year, with about 3000 new cases diagnosed annually. The male-to-female ratio is 1.3:1, and the average age of presentation is between 50 and 70 years.

**Etiology.** Risk factors associated with cholangiocarcinoma include primary sclerosing cholangitis, choleodochal cysts, ulcerative colitis, hepatolithiasis, biliary-enteric anastomosis, and biliary tract infections with *Clonorchis* or in chronic typhoid carriers. Features common to most risk factors include biliary stasis, bile duct stones, and infection. Other risk factors associated with cholangiocarcinoma are liver flukes, dietary nitrosamines, Thorotrast, and exposure to dioxin.

**Pathology.** Over 95% of bile duct cancers are adenocarcinomas. Morphologically, they are divided into nodular (the most common type), scirrhou, diffusely infiltrating, or papillary. Anatomically, they are divided into distal, proximal, or peri hilar tumors. Intrahepatic cholangiocarcinomas occur, but they are treated like hepatocellular carcinoma, with hepatectomy when possible. About two thirds of cholangiocarcinomas are located in the perihilar location. Perihilar cholangiocarcinomas, also referred to as Klatskin tumors, are further classified based on anatomic location by the Bismuth-Corlette classification (Fig. 32-26). Type I tumors are confined to the common

![Figure 32-26. Bismuth-Corlette classification of bile duct tumors.](image-url)
hepatic duct, but type II tumors involve the bifurcation without involvement of the secondary intrahepatic ducts. Type IIIa and IIIb tumors extend into the right and left secondary intrahepatic ducts, respectively. Type IV tumors involve both the right and left secondary intrahepatic ducts.

Clinical Manifestations and Diagnosis. Painless jaundice is the most common presentation. Pruritus, mild right upper quadrant pain, anorexia, fatigue, and weight loss also may be present. Cholangitis is the presenting symptom in about 10% of patients, but occurs more commonly after biliary manipulation in these patients. Except for jaundice, physical examination is usually normal in patients with cholangiocarcinoma. Occasionally, asymptomatic patients are found to have cholangiocarcinoma while being evaluated for elevated alkaline phosphatase and γ-glutamyltransferase levels. Tumor markers such as CA 125 and carcinoembryonic antigen can be elevated in cholangiocarcinoma but tend to be nonspecific because they also increase in other GI and gynecologic malignancies or cholangiopathologies. The tumor marker most commonly used to aid the diagnosis of cholangiocarcinoma is CA 19-9, which has a sensitivity of 79% and specificity of 98% if the serum value is >129 U/mL. However, mild elevations in CA 19-9 can be seen in cholangitis, other GI and gynecologic neoplasms, and patients who lack the Lewis blood type antigen.

The initial tests are usually ultrasound or CT scan. A perihepatic tumor causes dilatation of the intrahepatic biliary tree, but normal or collapsed gallbladder and extrahaephatic bile ducts distal to the tumor. Distal bile duct cancer leads to dilatation of the extra- and intrahepatic bile ducts as well as the gallbladder. Ultrasound can establish the level of obstruction and rule out the presence of bile duct stones as the cause of the obstructive jaundice (Fig. 32-27). It is usually difficult to visualize the tumor itself on ultrasound or on a standard CT scan. Either ultrasound or spiral CT can be used to determine portal vein patency. The biliary anatomy is defined by cholangiography. PTC defines the proximal extent of the tumor, which is the most important factor in determining resectability. ERC is used, particularly in the evaluation of distal bile duct tumors. For the evaluation of vascular involvement, celiac angiography may be necessary. With the newer types of MRI, a single noninvasive test has the potential of evaluating the biliary anatomy, lymph nodes, and vascular involvement, as well as the tumor growth itself.

Tissue diagnosis may be difficult to obtain nonoperatively except in advanced cases. Percutaneous fine-needle aspiration biopsy, biliary brush or scrape biopsy, and cytologic examination have a low sensitivity in detecting malignancy. Patients with potentially resectable disease should therefore be offered surgical exploration based on radiographic findings and clinical suspicion.

Treatment. Surgical excision is the only potentially curative treatment for cholangiocarcinoma. In the past one to two decades, improvements in surgical techniques have resulted in lower mortality and better outcome for patients undergoing aggressive surgical excision for cholangiocarcinoma.

Patients should undergo surgical exploration if they have no signs of metastasis or locally unresectable disease. However, despite improvements in ultrasonography, CT scanning, and MRI, more than one half of patients who are explored are found to have peritoneal implants, nodal or hepatic metastasis, or locally advanced disease that precludes resection. For these patients, surgical bypass for biliary decompression and cholecystectomy to prevent the occurrence of acute cholecystitis should be performed.

For unresectable perihilar cholangiocarcinoma, Roux-en-Y cholangiojejunostomy to either segment II or III bile ducts or to the right hepatic duct can be performed.

For curative resection, the location and local extension of the tumor dictates the extent of the resection. Perihilar tumors involving the bifurcation or proximal common hepatic duct (Bismuth-Corlette type I or II) with no signs of vascular involvement...
involvement are candidates for local tumor excision with portal lymphadenectomy, cholecystectomy, common bile duct excision, and bilateral Roux-en-Y hepaticojejunostomies. If the tumor involves the right or left hepatic duct (Bismuth-Corlette type IIIa or IIIb), right or left hepatic lobectomy, respectively, should also be performed. Frequently, resection of the adjacent caudate lobe is required because of direct extension into caudate biliary radicals or parenchyma.

Distal bile duct tumors are more often resectable. They are treated with pylorus-preserving pancreateoduodenectomy (Whipple procedure). For patients with distal bile duct cancer found to be unresectable on surgical exploration, Roux-en-Y hepaticojejunostomy, cholecystectomy, and gastrojejunostomy to prevent gastric outlet obstruction should be performed.

Nonoperative biliary decompression is performed for patients with unresectable disease on diagnostic evaluation. Percutaneous placement of expandable metal stents or drainage catheters is usually the appropriate approach for proximal tumors. However, for distal bile duct tumors, endoscopic placement is often the preferred approach (Fig. 32-28). There is a significant risk of cholangitis with internal and external drainage, and stent occlusion is not uncommon. However, although surgical bypass offers improved patency and fewer episodes of cholangitis, an operative intervention is not warranted in patients with metastatic disease.

There is no proven role for adjuvant chemotherapy in the treatment of cholangiocarcinoma. Adjuvant radiation therapy has also not been shown to increase either quality of life or survival in resected patients. Patients with unresectable disease often are offered treatment with 5-fluorouracil alone or in combination with mitomycin C and doxorubicin, but the response rates are low, <10% and <30%, respectively. The combination of radiation and chemotherapy may be more effective than either treatment alone for unresectable disease, but no data from randomized trials are available. Giving chemoradiation to these patients can be difficult because of the high incidence of cholangitis. External-beam radiation has not been shown to be an effective treatment for unresected disease. The use of interstitial (intraoperative) radiation, brachytherapy with iridium-192 via percutaneous or endoscopic stents, and combined interstitial and external-beam radiation for unresectable cholangiocarcinoma has been reported with some encouraging results. However, no randomized, prospective trials have been reported. A palliative measure that has been shown effective in a multicenter randomized trial is photodynamic therapy. In this trial, patients with a diagnosis of unresectable cholangiocarcinoma were randomized to biliary stenting with photodynamic therapy or stenting alone. The authors found that photodynamic therapy prolonged survival by approximately 400 days and improved quality of life on standardized questionnaire.

**Prognosis.** Most patients with perihilar cholangiocarcinoma present with advanced, unresectable disease. Patients with unresectable disease have a median survival between 5 and 8 months. The most common causes of death are hepatic failure and cholangitis. The overall 5-year survival rate for patients with resectable perihilar cholangiocarcinoma is between 10% and 30%, but for patients with negative margins, it may be as high as 40%.
The operative mortality for perihilar cholangiocarcinoma is 6% to 8%. Patients with distal cholangiocarcinoma are more likely to have resectable disease and improved prognosis compared to perihilar cholangiocarcinoma. The overall 3-year survival rate for resectable disease is 30% to 50%, and the median survival is 32 to 38 months.

The greatest risk factors for recurrence after resection are the presence of positive margins and lymph node–positive tumors. Therapy for recurrent disease is palliation of symptoms. Surgery is not recommended for patients with recurrent disease.

The pancreas is perhaps the most unforgiving organ in the human body, leading most surgeons to avoid even palpating it unless necessary. Situated deep in the center of the abdomen, the pancreas is surrounded by numerous important structures and major blood vessels. Seemingly minor trauma to the pancreas can result in the release of pancreatic enzymes and cause life-threatening pancreatitis. Therefore, knowledge of the relationships of the pancreas to surrounding structures is critically important for all surgeons to ensure that pancreatic injury is avoided during abdominal surgery.

**Gross Anatomy**

The pancreas is a retroperitoneal organ that lies in an oblique position, sloping upward from the C-loop of the duodenum to the splenic hilum (Fig. 33-1). In an adult, the pancreas weighs 75 to 100 g and is about 15 to 20 cm long. The fact that the pancreas is situated so deeply in the abdomen and is sealed in the retroperitoneum explains the poorly localized and sometimes ill-defined nature with which pancreatic pathology presents. Patients with pancreatic cancer without bile duct obstruction usually present after months of vague upper abdominal discomfort, or no antecedent symptoms at all. Due to its retroperitoneal location, pain associated with pancreatitis often is characterized as penetrating through to the back.

**Regions of the Pancreas**

Surgeons typically describe the location of pathology within the pancreas in relation to four regions: the head, neck, body, and tail. The head of the pancreas is nestled in the C-loop of the duodenum and is posterior to the transverse mesocolon. Just posterior to the head of the pancreas lie the vena cava, the right renal artery, and both renal veins. The neck of the pancreas lies directly anterior to the portal vein. At the inferior border of the neck of the pancreas, the superior mesenteric vein joins the splenic vein and then continues toward the porta hepatis as the portal vein. The inferior mesenteric vein often joins the splenic vein near its junction with the portal vein. Sometimes, the inferior mesenteric
venous branches draining the pancreatic head and uncinate process enter along the right lateral and posterior sides of the portal vein. There are usually no anterior venous tributaries, and a plane can usually be developed between the neck of the pancreas and the portal and superior mesenteric veins during pancreatic resection, unless the tumor is invading the vein anteriorly. The common bile duct runs in a deep groove on the back of the pancreas and is fed by multiple fragile venous branches from the pancreatic parenchyma. These branches must be divided to perform a spleen-sparing distal pancreatectomy. The splenic artery runs parallel and just superior to the vein along the posterior superior edge of the body and tail of the pancreas. The splenic artery often is tortuous. The anterior surface of the body of the pancreas is covered by peritoneum. Once the gastroduodenal omentum is divided, the body and tail of the pancreas can be seen along the floor of the lesser sac, just posterior to the stomach.

Pancreatic pseudocysts commonly develop in this area, and the posterior aspect of the stomach can form the anterior wall of the pseudocyst, allowing drainage into the stomach. The base of the transverse mesocolon attaches to the inferior margin of the body and tail of the pancreas. The transverse mesocolon often forms the inferior wall of pancreatic pseudocysts or inflammatory processes, allowing surgical drainage through the transverse mesocolon. The body of the pancreas is anterior to the splenic artery and vein. The vein runs in a
aorta at the origin of the superior mesenteric artery. The neck of the pancreas is anterior to the vertebral body of L1 and L2, and blunt anteroposterior trauma can compress the neck of the pancreas against the spine, causing parenchymal and, sometimes, ductal injury. The neck divides the pancreas into approximately two equal halves. The small portion of the pancreas anterior to the left kidney is referred to as the \textit{tail} and is nestled in the hilum of the spleen near the splenic flexure of the left colon. Awareness of these anatomic relationships is important to avoid injury to the pancreatic tail during left colectomy or splenectomy.

\textbf{Figure 33-1.} Pancreatic anatomy as seen on computed tomography. Knowledge of the relationship of the pancreas with surrounding structures is important to ensure that injury is avoided during abdominal surgery. IMV = inferior mesenteric vein; SMA = superior mesenteric artery; SMV = superior mesenteric vein.

\textbf{Figure 33-2.} Variations in portal venous anatomy. The superior mesenteric vein joins the splenic vein and then continues toward the porta hepatis as the portal vein. The inferior mesenteric vein often joins the splenic vein near its junction with the portal vein, but sometimes joins the superior mesenteric vein; or the three veins merge as a trifurcation to form the portal vein.
Pancreatic Duct Anatomy

An understanding of embryology is required to appreciate the common variations in pancreatic duct anatomy. The pancreas is formed by the fusion of a ventral and dorsal bud (Fig. 33-3). The duct from the smaller ventral bud, which arises from the hepatic diverticulum, connects directly to the common bile duct. The duct from the larger dorsal bud, which arises from the duodenum, drains directly into the duodenum. The duct of the ventral anlage becomes the duct of Wirsung, and the duct from the dorsal anlage becomes the duct of Santorini. With gut rotation, the ventral anlage rotates to the right and around the posterior side of the duodenum to fuse with the dorsal bud. The ventral anlage becomes the inferior portion of the pancreatic head and the uncinate process, while the dorsal anlage becomes the body and tail of the pancreas. The ducts from each anlage usually fuse together in the pancreatic head such that most of the pancreas drains through the duct of Wirsung, or main pancreatic duct, into the common channel formed from the bile duct and pancreatic duct. The length of the common channel is variable. In about one third of patients, the bile duct and pancreatic duct remain distinct to the end of the papilla, the two ducts merge at the end of the papilla in another one third, and in the remaining one third, a true common channel is present for a distance of several millimeters. Commonly, the duct from the dorsal anlage, the duct of Santorini, persists as the lesser pancreatic duct, and sometimes drains directly into the duodenum through the lesser papilla just proximal to the major papilla. In approximately 30% of patients, the duct of Santorini ends as a blind accessory duct and does not empty into the duodenum. In 10% of patients, the ducts of Wirsung and Santorini fail to fuse. This results in the majority of the pancreas draining through the duct of Santorini and the lesser papilla, while the inferior portion of the pancreatic head and uncinate process drains through the duct of Wirsung and major papilla. This normal anatomic variant, which occurs in one out of 10 patients, is referred to as pancreas divisum (Fig. 33-3). In a minority of these patients, the minor papilla can be inadequate to handle the flow of pancreatic juices from the majority of the gland. This relative outflow obstruction can result in pancreatitis and is sometimes treated by sphincteroplasty of the minor papilla.

The main pancreatic duct is usually only 2 to 3 mm in diameter and runs midway between the superior and inferior borders of the pancreas, usually closer to the posterior than to the anterior surface. Pressure inside the pancreatic duct is about twice that in the common bile duct, which is thought to prevent reflux of bile into the pancreatic duct. The main pancreatic duct joins with the common bile duct and empties at the ampulla of Vater or major papilla, which is located on the medial aspect of the second portion of the duodenum. The muscle fibers around the ampulla form the sphincter of Oddi, which controls the flow of pancreatic and biliary secretions into the duodenum. Contraction and relaxation of the sphincter is regulated by complex neural and hormonal factors. When the accessory pancreatic duct or lesser duct drains into the duodenum, a lesser papilla can be identified approximately 2 cm proximal to the ampulla of Vater.

Vascular and Lymphatic Anatomy

The blood supply to the pancreas comes from multiple branches from the celiac and superior mesenteric arteries (Fig. 33-4). The common hepatic artery gives rise to the gastroduodenal artery before continuing toward the porta hepatis as the proper hepatic artery. The right gastric artery branches off the gastroduodenal artery just superior to the duodenum. The gastroduodenal artery then travels inferiorly anterior to the neck of the pancreas and posterior to the duodenal bulb. A posterior ulcer in the duodenal bulb can erode into the gastroduodenal artery in this location. At the inferior border of the duodenum, the gastroduodenal artery then gives rise to the right gastroepiploic artery then continues on as the anterior superior pancreaticoduodenal artery, which branches into the anterior and posterior superior pancreaticoduodenal arteries. As the superior mesenteric artery passes behind the neck of the pancreas, it gives off the inferior pancreaticoduodenal artery at the inferior margin of the neck of the pancreas. This vessel quickly divides into the anterior and posterior inferior pancreaticoduodenal arteries. The superior and inferior pancreaticoduodenal arteries join together within the parenchyma of the anterior and posterior sides of the head of the pancreas along the medial aspect of the C-loop of the duodenum to form arcades that give off numerous branches to the duodenum and head of the pancreas. Therefore, it is impossible to resect the head of the
pancreas without devascularizing the duodenum, unless a rim of pancreas containing the pancreaticoduodenal arcade is preserved. Variations in the arterial anatomy occur in one out of five patients. The right hepatic artery, common hepatic artery, or gastroduodenal arteries can arise from the superior mesenteric artery. In 15% to 20% of patients, the right hepatic artery will arise from the superior mesenteric artery and travel upwards toward the liver along the posterior aspect of the head of the pancreas (referred to as a replaced right hepatic artery). It is important to look for this variation on preoperative computed tomographic (CT) scans and in the operating room so the replaced hepatic artery is recognized and injury is avoided. The body and tail of the pancreas are supplied by multiple branches of the splenic artery. The splenic artery arises from the celiac trunk and travels along the posterior-superior border of the body and tail of the pancreas toward the spleen. The inferior pancreatic artery usually arises from the superior mesenteric artery and runs to the left along the inferior border of the body and tail of the pancreas, parallel to the splenic artery. Three vessels run perpendicular to the long axis of the pancreatic body and tail and connect the splenic artery and inferior pancreatic artery. They are, from medial to lateral, the dorsal, great, and caudal pancreatic arteries. These arteries form arcades within the body and tail of the pancreas, and account for the rich blood supply of the organ.

The venous drainage of the pancreas follows a pattern similar to that of the arterial supply (Fig. 33-5). The veins are usually superficial to the arteries. Anterior traction on the transverse colon can tear fragile branches along the inferior border of the pancreas, which then retract into the parenchyma of the pancreas. Venous branches draining the pancreatic head and uncinate process enter along the right lateral and posterior sides of the portal vein. There are usually no anterior venous tributaries, and a plane can usually be developed between the neck of the pancreas and the portal and superior mesenteric veins.

Figure 33-4. Arterial supply to the pancreas. Multiple arcades in the head and body of the pancreas provide a rich blood supply. The head of the pancreas cannot be resected without devascularizing the duodenum unless a rim of pancreas containing the pancreaticoduodenal arcade is preserved.

Figure 33-5. Venous drainage from the pancreas. The venous drainage of the pancreas follows a pattern similar to the arterial supply, with the veins usually superficial to the arteries. Anterior traction on the transverse colon can tear fragile branches along the inferior border of the pancreas, which then retract into the parenchyma of the pancreas. Venous branches draining the pancreatic head and uncinate process enter along the right lateral and posterior sides of the portal vein. There are usually no anterior venous tributaries, and a plane can usually be developed between the neck of the pancreas and the portal and superior mesenteric veins.
superficial to the arteries within the parenchyma of the pancreas. There is an anterior and posterior venous arcade within the head of the pancreas. The superior veins drain directly into the portal vein just above the neck of the pancreas. The posterior inferior arcade drains directly into the inferior mesenteric vein at the inferior border of the neck of the pancreas. These venous tributaries must be divided during a Whipple procedure. The anterior inferior pancreaticoduodenal vein joins the right gastroepiploic vein and the middle colic vein to form a common venous trunk, which enters into the superior mesenteric vein. Traction on the transverse colon during colectomy can tear these fragile veins, which then retract into the parenchyma of the pancreas, making control tedious. There also are numerous small venous branches coming from the pancreatic parenchyma directly into the lateral and posterior aspect of the portal vein. Venous return from the body and tail of the pancreas drains into the splenic vein.

The lymphatic drainage from the pancreas is diffuse and widespread (Fig. 33-6). The profuse network of lymphatic vessels and lymph nodes draining the pancreas provides egress to tumor cells arising from the pancreas. This diffuse lymphatic drainage contributes to the fact that pancreatic cancer often presents with positive lymph nodes and a high incidence of local recurrence after resection. Lymph nodes can be palpated along the distal bile duct and posterior aspect of the head of the pancreas in the pancreaticoduodenal groove, where the mesenteric vein passes under the neck of the pancreas, along the inferior border of the body, at the celiac axis and along the hepatic artery ascending into the porta hepatis, and along the splenic artery and vein. The pancreatic lymphatics also communicate with lymph nodes in the transverse mesocolon and mesentery of the proximal jejunum. Tumors in the body and tail of the pancreas often metastasize to these nodes and lymph nodes along the splenic vein and in the hilum of the spleen.

**Neuroanatomy**

The pancreas is innervated by the sympathetic and parasympathetic nervous systems. The acinar cells responsible for exocrine secretion, the islet cells responsible for endocrine secretion, and the islet vasculature are innervated by both systems. The parasympathetic system stimulates endocrine and exocrine secretion and the sympathetic system inhibits secretion. The pancreas is also innervated by neurons that secrete amines and peptides, such as somatostatin, vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP), and galanin. The exact role of these neurons in pancreatic physiology is uncertain, but they do appear to affect both exocrine and endocrine function. The pancreas also has a rich supply of afferent sensory fibers, which are responsible for the intense pain associated with advanced pancreatic cancer, as well as acute and chronic pancreatitis. These somatic fibers travel superiorly to the celiac ganglia (Fig. 33-7). Interruption of these somatic fibers can stop transmission of pain sensation.

**HISTOLOGY AND PHYSIOLOGY**

The exocrine pancreas accounts for about 85% of the pancreatic mass; 10% of the gland is accounted for by extracellular matrix, and 4% by blood vessels and the major ducts, whereas only 2% of the gland is comprised of endocrine tissue. The endocrine and exocrine pancreases are sometimes thought of as functionally separate, but these different components of the organ are coordinated to allow an elegant regulatory feedback system for digestive enzyme and hormone secretion. This complex system regulates the type of digestion, its rate, and the processing and distribution of absorbed nutrients. This coordination is facilitated by the physical approximation of the islets and the exocrine pancreas, the presence of specific islet hormone receptors on the plasma membranes of pancreatic acinar cells, and the existence of an islet-acinar portal blood system.

Although patients can live without a pancreas when insulin and digestive enzyme replacement are administered, the loss of this islet-acinar coordination leads to impairments in digestive function. Although only approximately 20% of the normal pancreas is required to prevent insufficiency, in many patients undergoing pancreatic resection, the remaining pancreas is not normal, and pancreatic endocrine and exocrine insufficiency can develop with removal of smaller portions of the gland.

![Figure 33-6. Lymphatic supply to the pancreas. The lymphatic drainage from the pancreas is diffuse and widespread, which explains the high incidence of lymph node metastases and local recurrence of pancreatic cancer. The pancreatic lymphatics also communicate with lymph nodes in the transverse mesocolon and mesentery of the proximal jejunum. Tumors in the body and tail of the pancreas are often unresectable because they metastasize to these lymph nodes. Exocrine Pancreas

The pancreas secretes approximately 500 to 800 mL per day of colorless, odorless, alkaline, isosmotic pancreatic juice. Pancreatic juice is a combination of acinar cell and duct cell secretions. The acinar cells secrete amylase, proteases, and lipases, enzymes responsible for the digestion of all three food types: carbohydrate, protein, and fat. The acinar cells are pyramid-shaped, with their apices facing the lumen of the acinus. Near the apex of each cell are numerous enzyme-containing zymogen granules that fuse with the apical cell membrane (Fig. 33-8). Unlike the endocrine pancreas, where islet cells specialize in the secretion of one hormone type, individual acinar cells secrete all types of enzymes. However, the ratio of the different enzymes released is adjusted to the composition of digested food through nonparallel regulation of secretion.

Pancreatic amylase is secreted in its active form and completes the digestive process already begun by salivary amylase. Amylase is the only pancreatic enzyme secreted in its active form, and it hydrolyzes starch and glycogen to glucose, maltose, maltotriose, and dextrins. These simple sugars are transported across the brush border of the intestinal epithelial cells by active transport mechanisms. Gastric hydrolysis of protein yields peptides that enter the intestine and stimulate intestinal endocrine cells to release cholecystokinin (CCK)-releasing peptide, CCK, and secretin, which then stimulate the pancreas to secrete enzymes and bicarbonate into the intestine.

The proteolytic enzymes are secreted as proenzymes that require activation. Trypsinogen is converted to its active form, trypsin, by another enzyme, enterokinase, which is produced by the duodenal mucosal cells. Trypsin, in turn, activates the other proteolytic enzymes. Trypsinogen activation within the pancreas is prevented by the presence of inhibitors that are also secreted by the acinar cells. A failure to express a normal trypsinogen inhibitor, pancreatic secretory trypsin inhibitor (PSTI), also known as serine protease inhibitor Kazal type 1 (SPINK1), is a cause of familial pancreatitis. Inhibition of trypsinogen activation ensures that the enzymes within the pancreas remain in an inactive precursor state and are activated only within the duodenum. Trypsinogen is expressed in several isoforms, and a missense mutation on the cationic trypsinosin, or PRSS1, results in premature, intrapancreatic activation of trypsinosin. This accounts for about two-thirds of cases of hereditary pancreatitis. Chymotrypsinosin is activated to form chymotrypsin.
Elastase, carboxypeptidase A and B, and phospholipase are also activated by trypsin. Trypsin, chymotrypsin, and elastase cleave bonds between amino acids within a target peptide chain, and carboxypeptidase A and B cleave amino acids at the end of peptide chains. Individual amino acids and small dipeptides are then actively transported into the intestinal epithelial cells. Pancreatic lipase hydrolyzes triglycerides to 2-monoglyceride and fatty acid. Pancreatic lipase is secreted in an active form. Colipase is also secreted by the pancreas and binds to lipase, changing its molecular configuration and increasing its activity. Phospholipase A2 is secreted by the pancreas as a proenzyme that becomes activated by trypsin. Phospholipase A2 hydrolyzes phospholipids and, as with all lipases, requires bile salts for its action. Carboxylic ester hydrolase and cholesterol esterase hydrolyze neutral lipid substrates like esters of cholesterol, fat-soluble vitamins, and triglycerides. The hydrolyzed fat is then packaged into micelles for transport into the intestinal epithelial cells, where the fatty acids are reassembled and packaged inside chylomicrons for transport through the lymphatic system into the bloodstream (Table 33-1).

The centroacinar and intercalated duct cells secrete the water and electrolytes present in the pancreatic juice. About 40 acinar cells are arranged into a spherical unit called an acinus. Centroacinar cells are located near the center of the acinus and are responsible for fluid and electrolyte secretion. These cells contain the enzyme carbonic anhydrase, which is needed for bicarbonate secretion. The amount of bicarbonate secreted varies with the pancreatic secretory rate, with greater concentrations of bicarbonate being secreted as the pancreatic secretory rate increases. Chloride secretion varies inversely with bicarbonate secretion such that the sum of these two remains constant. In contrast, sodium and potassium concentrations are kept constant throughout the spectrum of secretory rates (Fig. 33-9). The hormone secretin is released from cells in the duodenal mucosa in response to acidic chyme passing through the pylorus into the duodenum. Secretin is the major stimulant for bicarbonate secretion, which buffers the acidic fluid entering the duodenum from the stomach. CCK also stimulates bicarbonate secretion, but to a much lesser extent than secretin. CCK potentiates secretin-stimulated bicarbonate secretion. Gastrin and acetylcholine, both stimulants of gastric acid secretion, are also weak stimulants of pancreatic bicarbonate secretion. Truncal vagotomy produces a myriad of complex effects on the downstream digestive tract, but the sum effect on the exocrine pancreas is a reduction in bicarbonate and fluid secretion. The endocrine pancreas also influences the adjacent exocrine pancreatic secretions. Somatostatin, pancreatic polypeptide (PP), and glucagon are all thought to inhibit exocrine secretion. The acinar cells release pancreatic enzymes from their zymogen granules into the lumen of the acinus, and these proteins combine with the water and bicarbonate secretions of the centroacinar cells. The pancreatic juice then travels into small intercalated ducts. Several small intercalated ducts join to form an interlobular duct. Cells in the interlobular ducts contribute fluid and electrolytes to adjust the final concentrations of the pancreatic fluid. Interlobular ducts then join to form about 20 secondary ducts that empty into the main pancreatic duct. Destruction of the branching ductal tree from recurrent inflammation, scarring, and deposition of stones eventually contributes to destruction of the exocrine pancreas and exocrine pancreatic insufficiency.

### Endocrine Pancreas

There are nearly 1 million islets of Langerhans in the normal adult pancreas. They vary greatly in size from 40 to 900 μm. Larger islets are located closer to the major arterioles and smaller islets are embedded more deeply in the parenchyma of the pancreas. Most islets contain 3000 to 4000 cells of five major types: alpha cells that secrete glucagon, beta cells that secrete insulin, delta cells that secrete somatostatin, epsilon cells that secrete ghrelin, and PP cells that secrete PP (Table 33-2).

Insulin was subsequently purified and found to be a 56-amino acid peptide with two chains, an \( \alpha \) and a \( \beta \) chain, joined by two disulfide bridges and a connecting peptide, or C-peptide. Pro-insulin is made in the endoplasmic reticulum and then is transported to the Golgi complex, where it is packaged into granules and the C-peptide is cleaved off. There are two phases of insulin secretion. In the first phase, stored insulin is released. This phase lasts about 5 minutes after a glucose challenge. The second phase of insulin secretion is a longer, sustained release due to ongoing production of new insulin. \( \beta \)-cell synthesis of insulin is regulated by plasma glucose levels, neural signals, and the paracrine influence of other islet cells. The diagnosis of diabetes is made by using oral and intravenous (IV) glucose tolerance tests. Oral glucose not only enters the bloodstream but also stimulates the release of other hormones such as gastric inhibitory peptide (also known as glucose-dependent insulinotropic polypeptide or GIP), glucagon-like peptide-1 (GLP-1), and CCK that augment the secretion of insulin, and are therefore referred to as incretins. As a result, oral glucose is a more vigorous stimulus to insulin secretion than IV glucose. In the oral glucose tolerance test (OGTT), the patient is fasted overnight, and a basal glucose value is determined. Forty g/m\(^2\) or 75 g of glucose is given orally over 10 minutes. Blood samples are taken every 30 minutes for 2 hours. Normal values and criteria for diabetes vary by age, but essentially all values should be <200 mg/dL, and the 120-minute value should be <140 mg/dL.

Insulin secretion by the \( \beta \)-cell is also influenced by plasma levels of amino acids such as arginine, lysine, leucine, and free fatty acids. Glucagon, GIP, GLP-1, and CCK stimulate insulin release, while somatostatin, amylin, and pancreastatin inhibit insulin release. Cholinergic fibers and beta sympathetic fibers stimulate insulin release, while alpha sympathetic fibers inhibit insulin secretion.

Insulin’s glucoregulatory function is to inhibit endogenous (hepatic) glucose production and to facilitate glucose transport.

Glucagon is a 29-amino-acid, single-chain peptide that promotes hepatic glycogenolysis and gluconeogenesis and counteracts the effects of insulin through its hyperglycemic action. Glucose is the primary regulator of glucagon secretion, as it is with insulin, but it has an inhibitory rather than stimulatory effect. Glucagon release is stimulated by hypoglycemia, and by the amino acids arginine and alanine. GLP-1 inhibits glucagon secretion in vivo, and insulin and somatostatin inhibit glucagon secretion in a paracrine fashion within the islet. The same neural impulses that regulate insulin secretion also regulate glucagon secretion, so that the two hormones work together in a balance of actions to maintain glucose levels. Cholinergic and beta sympathetic fibers stimulate glucagon release, while alpha sympathetic fibers inhibit glucagon release.8 In pancreaticogenic or type 3c diabetes, glucagon responsiveness to a fall in blood glucose is lost, thereby increasing the risk for hypoglycemia.

Although originally isolated from the hypothalamus, somatostatin is a peptide that is now known to have a wide anatomic distribution, not only in neurons but also in the pancreas, gut, and other tissues. It is a highly conserved peptide hormone, as it is found in lower vertebrates, and is now realized to be of fundamental importance in regulatory processes throughout the body. One gene encodes for a common precursor that is differentially processed to generate tissue-specific amounts of two bioactive products, somatostatin-14, and somatostatin-28. These peptides inhibit endocrine and exocrine secretion and affect neurotransmission, GI and biliary motility, intestinal absorption, vascular tone, and cell proliferation.

Five different somatostatin receptors (SSTRs) have been cloned and the biologic properties of each are being unraveled.9 All five are G-protein-coupled receptors with seven highly conserved transmembrane domains and unique amino and carboxy termini. Phosphorylation sites located within the second and third intracellular loops and in the cytoplasmic C-terminal segment are thought to mediate receptor regulation. Although the naturally occurring peptides bind to all five receptors, somatostatin-28 is relatively selective for SSTR5. The hexapeptide and octapeptide analogues such as octreotide bind only to SSTR2, SSTR3, and SSTR5. These analogues have a longer serum half-life, and their potent inhibitory effect has been used clinically to treat both endocrine and exocrine disorders. For example, octreotide has been shown to decrease fistula output and speed the time it takes for enteric and pancreatic fistulas to close.10

Endocrine release of somatostatin occurs during a meal. The major stimulant is probably intraluminal fat. Acidification of the gastric and duodenal mucosa also releases somatostatin in isolated perfused organ preparations. Acetylcholine from the cholinergic neurons inhibits somatostatin release.

Pancreatic polypeptide (PP) is a 36-amino-acid, straight-chain peptide discovered by Kimmel in 1968 during the process of insulin purification. Protein is the most potent enteral stimulator of PP release, closely followed by fat, whereas glucose has a weaker effect.11 Hypoglycemia, whether or not it is insulin...
Induced, strongly stimulates PP secretion through cholinergic stimulation. Phenylalanine, tryptophan, and fatty acids in the duodenum stimulate PP release, probably by inducing CCK and secretin release. In the isolated perfused pancreas, insulin and gastric inhibitory peptide stimulate PP release, while glucagon and somatostatin inhibit it. Vagal stimulation of the pancreas is the most important regulator of PP secretion. In fact, vagotomy eliminates the rise in PP levels usually seen after a meal. This can be used as a test for the completeness of a surgical vagotomy or for the presence of diabetic autonomic neuropathy.

PP has been shown to inhibit choleris (bile secretion), gallbladder contraction, and secretion by the exocrine pancreas. However, PP’s most important role is in glucose regulation through its regulation of hepatic insulin receptor gene expression. A deficiency in PP secretion due to proximal pancreatico-duodenectomy, severe chronic pancreatitis, or cystic fibrosis is associated with diminished hepatic insulin sensitivity due to reduced hepatic insulin receptor availability. This effect is reversed by PP administration.

Recent studies have shown that a fifth islet peptide, ghrelin, is secreted from a distinct population of islet cells, called epsilon cells. Ghrelin also is present in the gastric fundus in large amounts and stimulates growth hormone secretion via growth hormone releasing hormone release from the pituitary. It is an orexigenic, or appetite-stimulating, peptide the plasma levels of which are increased in obesity. Ghrelin has also been shown to block insulin effects on the liver, and inhibits the beta-cell response to incretin hormones and glucose. Therefore, ghrelin secretion from and within the islet may modulate the responses of other islet cells to nutrient and hormonal stimuli.

In addition to the five main peptides secreted by the pancreas, there are a number of other peptide products of the islet cells, including amylin and pancreastatin, as well as neuropeptides such as VIP, galanin, and serotonin. Amylin or islet amyloid polypeptide (IAPP) is a 37-amino-acid polypeptide that is predominantly expressed by the pancreatic beta-cells, where it is stored along with insulin in secretory granules. The function of IAPP seems to be the modulation or counterregulation of insulin secretion and function. Pancreastatin is a recently discovered pancreatic islet peptide product that inhibits insulin, and possibly somatostatin release, and augments glucagon release. In addition to this effect on the endocrine pancreas, pancreastatin inhibits pancreatic exocrine secretion.

**Islet Distribution**

The beta-cells are generally located in the central portion of each islet and make up about 70% of the total islet cell mass. The other cell types are located predominantly in the periiphery. The delta cells are least plentiful, making up only 5%; the alpha-cells make up 10%; and the PP cells make up 15%. In contrast to the acinar cells that secrete the full gamut of exocrine enzymes, the islet cells seem to specialize in the secretion of predominantly one hormone. However, individual islet cells can secrete multiple hormones. For example, the beta-cells secrete both insulin and amylin, which counterregulates the actions of insulin. In reality, more than 20 different hormones are secreted by the islets, and the exact functions of this milieu are very complex. There is diversity among the islets depending on their location within the pancreas. The delta- and delta-cells are evenly distributed throughout the pancreas, but islets in the head and uncinate process (ventral anlage) have a higher percentage of PP cells and fewer alpha-cells, whereas islets in the body and tail (dorsal anlage) contain the majority of alpha-cells and few PP cells. This is clinically significant because pancreatoduodenectomy removes 95% of the PP cells in the pancreas. This may partially explain the higher incidence of glucose intolerance after the Whipple procedure compared to a distal pancreatectomy with an equivalent amount of tissue resected. In addition, chronic pancreatitis, which disproportionately affects the pancreatic head, is associated with PP deficiency and pancreaticogenic diabetes. The relative preponderance of alpha-cells in the body and tail of the pancreas explains the typical location of glucagonomas.

**ACUTE PANCREATITIS**

**Definition, Incidence, and Epidemiology**

Acute pancreatitis is a common and challenging disease that can develop both local and systemic complications. Its hallmark is acute pancreatic inflammation associated with little or no fibrosis. It ranges from a mild self-limiting inflammation of the pancreas to critical disease characterized by infected pancreatic necrosis, multiple organ failure and a high risk of mortality. The clinical outcome has improved over recent decades, even in the absence of specific treatments that target outcome-determining pathophysiology, probably because of a more consistent approach to diagnosis, monitoring and management.

Acute pancreatitis is the most common gastrointestinal discharge diagnosis in the United States (274,119 patients in 2009), an incidence which has increased 30% since 2000, and is associated with the highest aggregate inpatient costs at 2.6 billion dollars per year. The crude mortality rate of 1.0/100,000 ranks it as the 14th most fatal illness overall and the ninth most common noncancer gastrointestinal death. Worldwide the incidence of acute pancreatitis ranges from 5 to 80/100,000 population with the highest incidence recorded in Finland and United States. The racial incidence of acute pancreatitis also shows significant variation related to the prevalence of etiological factors and ethnicity. The annual incidence of acute pancreatitis in Native Americans is 4 per 100,000 population; in whites it is 5.7 per 100,000 population; and in blacks it is 20.7 per 100,000 population. Smoking is an independent risk factor for acute pancreatitis.

**Etiology**

Many factors have been causally related to the onset of acute pancreatitis (Table 33-4), but in many instances the mechanism is poorly understood. The most common causes are gallstones and alcohol, accounting for up to 80% of cases, but it is not uncommon to diagnose acute pancreatitis in the absence of these etiological factors. Therefore it is important that a systematic approach is taken to the identification of other, less common, and potentially modifiable, factors. The median age of the onset of acute pancreatitis varies with etiology: alcohol and drug induced pancreatitis typically present in the third or fourth decade compared with gallstone and trauma induced disease in the sixth decade. The gender difference is probably more related to etiology: in males alcohol is more often the cause while in females it is gallstones.

**Gallstones**

Evidence that passage of a gallstone is related to the onset of acute pancreatitis comes from the characteristic transient derangement of liver function tests and the high retrieval rate
The mechanism by which small gallstones are associated with acute pancreatitis is probably responsible for up to half of those with idiopathic acute pancreatitis. Alcohol ingestion is associated with recurrent acute pancreatitis, seen as birefringent crystals, on bile microscopy. This occult microlithiasis is probably responsible for up to half of those with idiopathic acute pancreatitis.

Alcohol

Alcohol ingestion is associated with acute pancreatitis and sustained alcohol ingestion is associated with recurrent acute pancreatitis and development of chronic pancreatitis in susceptible individuals who have been drinking for more than a decade. The type of alcohol consumed is less important than the amount consumed (typically 100 to 150 grams per day) and the pattern of drinking. It is common for patients with alcohol associated acute pancreatitis to have a history of excess alcohol consumption prior to the first attack. There are several mechanisms by which ethanol causes acute pancreatitis. Ethanol is a metabolic toxin to pancreatic acinar cells and causes a brief secretory increase followed by inhibition. The secretory burst coupled with ethanol induced spasm of the sphincter of Oddi is thought to incite acute pancreatitis. Ethanol also induces ductal permeability, which would allow prematurely activated enzymes to cause damage to the pancreatic parenchyma. Ethanol also increases the protein content of pancreatic juice, decreases bicarbonate levels, and trypsin inhibitor concentration.

Idiopathic

Acute pancreatitis can result from a number of treatments, including pancreatic biopsy, exploration of the extrahepatic biliary tree and ampulla of Vater, distal gastrectomy, splenectomy, colectomy, nephrectomy, aortic aneurysmorrhaphy, and retroperitoneal lymphadenectomy. As the pancreas is susceptible to ischemia it can also occur secondary to splanchic hypoperfusion with cardio-pulmonary bypass or cardiac transplant. Most commonly, acute pancreatitis occurs as a complication of ERCP in 5% to 10% of procedures, and in many series it is the third most common identified etiological factor. The risk of post-ERCP acute pancreatitis is increased if the contrast agent is infused repeatedly under high pressure by the endoscopist and in patients with sphincter of Oddi dysfunction. Recent evidence demonstrates that the risk can be decreased with prophylactic, rectally administered, nonsteroidal drugs.

Hereditary Pancreatitis

Hereditary pancreatitis is an autosomal dominant disorder usually related to mutations of the cationic trypsinogen gene (PRSS1). Mutations in this gene cause premature activation of trypsinogen to trypsin and cause abnormalities of ductal secretion, both of which promote acute pancreatitis. Mutations in the SPINK1 protein, which blocks the active binding site of trypsin, is also likely to have a role in predisposing to acute pancreatitis. Variations in penetration and phenotype are common and there are many other mutations that may become implicated. Mutant enzymes activated within acinar cells can overwhelm the first line of defense (pancreatic secretory trypsin inhibitor) and resist backup defenses (e.g., proteolytic degradation, enzyme Y, and trypsin itself) allowing activated mutant cationic trypsin to trigger the entire zymogen activation cascade.

Tumors

A pancreatic or periampullary tumor should be considered in any patient with idiopathic acute pancreatitis. Approximately 1% to 2% of patients with acute pancreatitis have a pancreatic tumor, and an episode of acute pancreatitis can be the first clinical manifestation of the tumor. If no historical information leads to an etiologic diagnosis, cross sectional pancreatic imaging after the resolution of an unexplained episode of acute pancreatitis is indicated.

Hyperlipidemia

Patients with types I and V hyperlipoproteinemia can experience episodes of abdominal pain, and these often occur in association with marked hypertriglyceridaemia. Lipase is thought to liberate...
toxic fatty acids into the pancreatic microcirculation, leading to microcirculatory impairment and ischemia. Dietary modifications to restrict triglycerides are usually effective, but clofibrate may be prescribed in refractory cases of hypertriglyceridemia.

**Drugs and Miscellaneous Causes**

Many drugs can produce hyperamylasemia and/or abdominal pain, and a drug is considered suspect if the pancreatitis-like illness resolves with its discontinuation. Ethical considerations generally rule out rechallenge with the suspect drug, so the connection often remains vague. However, despite these limitations, certain drugs are known to be capable of causing acute pancreatitis. These include the thiazide diuretics, furosemide, estrogens, azathioprine, l-asparaginase, 6-mercaptopurine, methyl dopa, the sulfonamides, tetracycline, pentamidine, procainamide, nitrofurantoin, dideoxyinosine, valproic acid, and acetylcholinesterase inhibitors. In addition, lipid-based intravenous drugs and solutions, such as propofol, can also cause acute pancreatitis. A history of verified or suspected drug-induced pancreatitis should serve as a contraindication to prescribing that medication again.

Hypercalceric states arising from hyperparathyroidism can result in both acute and chronic pancreatitis; the mechanism most likely involves hypersecretion and the formation of calcified stones intraductally. Also implicated are infestations by *Ascaris lumbricoides* and the liver fluke *Clonorchis sinensis*, which is endemic to China, Japan, and Southeast Asia. These cause Oriental cholangitis, which is associated with cholangiocarcinoma obstructing the pancreatic duct.

Other implicated factors include azotemia, vasculitis, and the sting of the Trinidadian scorpion *Tityus trinitatis*. This scorpion’s venom has been shown to cause neurotransmitter discharge from cholinergic nerve terminals, leading to massive production of pancreatic juice. Poisoning with antiacetylcholinesterase insecticides has a similar effect. Finally, no apparent cause can be ascribed to some episodes of acute pancreatitis, and these constitute the group referred to as idiopathic.

**Pathophysiology**

Acute pancreatitis occurs in various degrees of severity, the determinants of which are multifactorial. The generally prevalent belief today is that pancreatitis begins with the activation of digestive zymogens inside acinar cells, which cause acinar cell injury. Studies suggest that the ultimate severity of the resulting pancreatitis may be determined by the events that occur subsequent to acinar cell injury. These include inflammatory cell recruitment and activation, as well as generation and release of cytokines and other chemical mediators of inflammation (Fig. 33-10).

**Precipitating Initial Events**

**Acinar Cell Events.** Acute pancreatitis is an inflammatory disorder believed to begin in the pancreas and is generally restricted to it; although in some cases its effects can be systemic, diverse and result in multiple organ failure. In 1896, Chiari advanced the understanding of acute pancreatitis by proposing the concept that the pancreatitis is essentially the premature, intrapancreatic activation of digestive enzymes, resulting in auto-digestion of the organ. Since then the intra-acinar activation of zymogens has been demonstrated consistently in multiple animal models of acute pancreatitis and is considered a central piece in the puzzle of acute pancreatitis. The key role of trypsin activation in acute pancreatitis has gained additional support from recent studies showing that mice lacking trypsinogen-7 (the isoform of trypsinogen which is activated during acute pancreatitis in mice) have significantly less pancreatic injury during acute pancreatitis and that intra-acinar expression of active trypsin causes pancreatitis in mice. The role of trypsin activation in the pathophysiology of acute pancreatitis has also been suggested by clinical studies; e.g., hereditary pancreatitis is associated with mutations that lead to elevated intracellular trypsin activation and activation of trypsinogen has been demonstrated in clinical pancreatitis as well.
The mechanisms by which injurious stimuli lead to intracellular activation of trypsinogen and autodigestion of the gland have been the focus of research in pancreatitis for decades. Because the exocrine pancreas produces enzymes that are potentially injurious to it, several protective mechanisms have evolved to prevent autodigestion under normal conditions. Enzymes are synthesized as inactive precursors called proenzymes orzymogens, which are then transported and secreted outside the gland. Their activation occurs safely in the duodenum, where the brush-border enzyme enteroprotease (or enterokinase) activates the trypsinogen, and the resulting trypsin then activates the otherzymogens in a cascade reaction. This separates the site of production of these enzymes from the site of activation and thus the pancreas is insulated against enzymatic attack. Within the acinar cell itself, the potentially harmful digestive enzymes are segregated from the surrounding cytoplasm by being enclosed within membrane-bound organelles referred to aszymogen granules. Another layer of protection is provided by the synthesis of trypsin inhibitors, which are transported and stored along with the digestive enzymezymogens. These are available to inhibit small amounts of prematurely-activated trypsinogen within the pancreatic acinar cells. It is theorized that acute pancreatitis occurs when this process goes awry and the gland is injured by the erroneously-activated enzymes that it produces. Although the mechanism(s) of erroneous activation are not fully understood, it has been shown that intracinar activation of trypsinogen goes hand-in-hand with inhibition of acinar secretion.41, 42 Furthermore, in the presence of injurious stimuli, thezymogens responsible for initiating the disease are not secreted outside, but are observed to co-localize with cytoplasmic vacuoles that containzymosomal enzymes such aszymase B.43 Data suggest thatzymase B in these vacuoles activateszymogen. Thus, inhibition ofzymase B by pharmacological inhibitors44 or by genetic deletion ofzymase B eliminates trypsin activation and decreases the severity ofpancreatitis in animal models.45 What leads to the coming together ofzymogens andzymosomal hydrolases is unclear, but injurious stimuli leading to sustained cytosolic calcium increase have been indicted. Blocking this calcium increase prevents colocalization and activation ofzymase, and decreases injury due to pancreatitis.46 Based on these data, pre-ERCP supplementation of magnesium, a natural antagonist of calcium, is currently being evaluated as a strategy to decrease post-ERCP pancreatitis.47 How activation ofzymase in the co-localization vacuoles leads to pancreatic damage is also not clear. Recent work has led to the novel hypothesis that thezymosomal hydrolasezymase B activateszymogen tozym within the co-localization vacuoles. Trypsin then permeabilizes these co-localization vacuoles causing the release ofzymase B into the cytosol. Once in thecytosol,zymase Binitiates apoptotic cell death by permeabilizing mitochondrial membranes, which allows cytochrome C to be released into thecytosol. This initiates the apoptotic cascade and results in the apoptotic death of theacinar cells (Fig. 33-11).48

**Intrapancreatic Events**

Activated neutrophils are attracted to a focus of tissue injury and after activation release superoxides (the “respiratory burst”) and proteolyticenzymes (zymases, elastase and collagenase) which cause further injury. In addition macrophages release cytokines (including tumor necrosis factor-alpha (TNF-α), interleukin (IL)-6, and IL-8) which mediate the local and the systemic inflammatory responses. These inflammatory mediators cause an increased pancreatic vascular permeability, leading to edema, hemorrhage, andmicrothrombi. Fluid may collect in and around the pancreas. The failure of the pancreatic microcirculation, a feature of more severe acute pancreatitis, results in pancreatic hyperperfusion and necrosis. Acute inflammation of thepancreatic parenchyma and peripancreatic tissues, but without recognizable necrosis is termedinterstitial edematouspancreatitis.49 When necrosis is present, and evidenced by pancreatic hyperperfusion with constrast CT, it is termednecrotizingpancreatitis (Fig. 33-12). The updated morphological definitions and the contrast enhanced CT criteria for the diagnosis of thelocal complications of acute pancreatitis have recently been published in the revised Atlanta statement,50 and summarized in Table 33-5.51

Figure 33-11. Schematic representation of the acinar cell events in acute pancreatitis. When acinar cells are pathologically stimulated, theirzymosomal (L) andzymogen (Z) contents colocalize, consequentlyzymogen is activated tozym byzymase B. Increased cytosolic calcium is required for colocalization. Oncezym has permeabilized the contents of thecytosol,zymase B and other contents of these colocalized organelles are released. Once in thecytosol,zymase B activates apoptosis by causing cytochrome c to be released from the mitochondria. Activation of PKC results in a sudden activation of nuclear factor kappa beta (NFκB) which in turn triggers the release of cytokines that attract inflammatory response cells which mediate local and systemic inflammation cascades.52
Systemic Events
An important aspect of the pathophysiology of acute pancreatitis is the mechanism by which events occurring in the pancreas induce systemic inflammation and multiorgan failure. The NFκB-dependent inflammatory pathway is one such key pathway. NFκB activation parallels trypsin activation in acute pancreatitis but appears to be independent of it. The role of trypsin in NFκB activation was debated for a long time, but this issue seems to be largely settled following the observation that NFκB activation still occurs in acini from trypsin knockout mice, which obviously do not have pathologic trypsin activation. However, sustained calcium increase, which leads to trypsinogen activation, is critical for NFκB activation as well, since attenuation of cytosolic calcium also abrogates NFκB activation. Once activated, NFκB regulates synthesis of multiple cytokines and chemokines, leading to recruitment of various inflammatory cells that then magnify and propagate systemic inflammation.

Although intra-acinar events initiate acute pancreatitis, events occurring subsequent to acinar cell injury determine the severity of pancreatitis. Once recruited to the pancreas, various inflammatory cells lead to further acinar cell injury and cause an elevation of various pro-inflammatory mediators such as TNF-α, IL-1, IL-2, IL-6, and other chemokines and anti-inflammatory factors. Elucidation of these mediators has encouraged efforts to target their production or activity with an aim to modulate the course of severe acute pancreatitis.

Organ failure can develop at any stage of acute pancreatitis, associated with an overwhelming proinflammatory response early, or later secondary to the development of infected local complications. The drivers of the systemic response are poorly understood, although factors include the elaboration of proinflammatory cytokines, and it appears that mesenteric lymph, bypassing the liver and containing these constituents, may contribute to the development of organ failure. The development of pancreatic necrosis, the breakdown of the intestinal barrier and the suppression of the immune response through the compensatory inflammatory response contribute to the development of infected necrotic pancreatitis, the incidence of which peaks in the third to fourth week. This is usually associated with deterioration in the patient and may be associated with the late development of the systemic inflammatory response syndrome (SIRS) and multiorgan dysfunction syndrome/failure (MODS/F).

Organ failure is scored using the Marshall or Sequential Organ Failure Assessment (SOFA) systems (Table 33-6). The three organ systems most frequently involved are cardiovascular, respiratory, and renal. Multiple organ failure is defined as two or more organs registering 2 or more points on these scoring systems. Monitoring organ failure over time and in response to treatment is important in the clinical care of the disease.

### Management of the Patient

#### General Considerations
The management of acute pancreatitis covers a wide spectrum of severity. Patients with suspected acute pancreatitis should be admitted to hospital. Those with mild acute pancreatitis usually remain in hospital for less than a week, while those with severe and critical acute pancreatitis may require many weeks or months of intensive treatment. The risk of mortality reflects this spectrum of severity. The risk is less than 1% for those with mild disease, increasing to around 10% for those with moderate disease, but for severe and critical disease the mortality risk is much higher (20% to 40% and greater than 50%, respectively). The earlier identification of these high-risk categories and the transfer of these patients to specialized centers is an important priority of management. Scoring systems such as Ranson’s Criteria identify these high-risk patients (Table 33-7). The management of acute pancreatitis should be multidisciplinary and it is important that a coordinated care plan is carefully supervised.

#### Diagnosis
The diagnosis of acute pancreatitis requires the patient to present with abdominal pain consistent with acute pancreatitis (acute onset of a severe constant epigastric pain which often radiates through to the mid back) and the elevation of serum amylase or lipase (>3 times upper limit of normal). Imaging (usually by contrast enhanced CT scanning) is only required for the diagnosis of acute pancreatitis when these diagnostic criteria are not met. Because of the many causes of hyperamylasemia,
During the initial 48 h

it is important to measure either the pancreatic isoenzyme of amylase or lipase.

The serum amylase concentration increases almost immediately with the onset of disease and peaks within several hours. It remains elevated for 3 to 5 days before returning to normal. There is no significant correlation between the magnitude of serum amylase elevation and severity of pancreatitis; in fact, a milder form of acute pancreatitis is often associated with higher levels of serum amylase compared with that in a more severe form of the disease.

It is important to note that hyperamylasemia can also occur as a result of conditions not involving pancreatitis. For example, hyperamylasemia can occur in a patient with small bowel obstruction, perforated duodenal ulcer, or other intra-abdominal inflammatory conditions. In contrast, a patient with acute pancreatitis may have a normal serum amylase level, which could be due to several reasons. In patients with hyperlipidemia, values might appear to be normal because of interference by lipids with chemical determination of serum amylase. In many cases, urinary amylase levels usually remain elevated for several days after serum levels have returned to normal. In patients with severe pancreatitis associated with significant necrotic damage, the pancreas may not release large amounts of enzymes into the circulation.

With increasing severity of disease, the intravascular fluid loss may become life-threatening as a result of sequestration of edematous fluid in the retroperitoneum. Hemoconcentration then results in an elevated hematocrit. However, there also may be bleeding into the retroperitoneum or the peritoneal cavity. In some patients (about 1%), the blood from necrotizing pancreatitis may dissect through the soft tissues and manifest itself as a bluish discoloration around the umbilicus (Cullen’s sign) or in the flanks.

AST = aspartate transaminase; BUN = blood urea nitrogen; LDH = lactate dehydrogenase; PO_2 = partial pressure of oxygen; WBC = white blood cell count.

**Note:** Fewer than 3 positive criteria predict mild, uncomplicated disease whereas more than 6 positive criteria predict severe disease with a mortality risk of 50%

(Grey Turner’s sign). The severe fluid loss may lead to prerenal azotemia with elevated blood urea nitrogen and creatinine levels. There also may be hyperglycemia, hypoalbuminemia, and hypocalcemia sufficient in some cases to produce tetany.

**Pain Management**

Pain is the cardinal symptom of acute pancreatitis and its relief is a clinical priority. There is a lack of high quality evidence to guide the choice of analgesics. Because of unpredictable absorption analgesia should be administered intravenously, at least at the outset and before oral intake has been established. Those with mild pain can usually be managed with a nonsteroidal anti-inflammatory drug (e.g., metamizole 2g/8h IV) while those with more severe pain are best managed with opioid analgesia (e.g., buprenorphine 0.3mg/4h IV). Administration of buprenorphine, pentazocine, procaine hydrochloride, and meperidine are all of value in controlling abdominal pain. Morphine is to be avoided, due to its potential to cause sphincter of Oddi spasm.

**Predicting Severity**

Where classification relates to the present or past severity of acute pancreatitis, prediction is about the future and ultimate severity and outcome of the patient. Accurately predicting acute pancreatitis severity is important in making triage decisions about whether a patient should be transferred to a tertiary hospital, or admitted to an intensive care unit, and in making decisions about fluid therapy, whether an ERCP is indicated, and other issues. There is a long history of attempts to find prognostic or predictive markers that accurately stratify the risk, with the most widely used being the Ranson’s criteria (Table 33-7) or modified Glasgow criteria. Both use clinical and biochemical parameters scored over the first 48 hours of admission. When there are 3 or more positive criteria, the disease is considered “predicted severe.” There are many other approaches to predicting severity. At 24 hours after admission an APACHE II score of 8 or more or a serum C-reactive protein level of >150mg/dl has a similar accuracy in predicting severity as Ranson’s criteria. The more recently proposed Bedside Index for Severity of Acute Pancreatitis (BISAP) is calculated from blood urea nitrogen (> 25 mg/dl), impaired mental status (GCS <15), presence of systemic inflammatory response syndrome (SIRS), age >60 years, and pleural effusion. Although it has the advantage of simplicity and can be performed within the first 24 hours of admission it has performed no better than other predictors in comparison studies. The presence of SIRS also has prognostic significance. There remains some controversy as to the importance of obesity as a risk factor for severe and critical acute pancreatitis. Another approach has been in seeking to predict those with ‘harmless’ acute pancreatitis using three factors that can be determined on admission; absence of rebound tenderness or guarding, normal hematocrit, and normal serum creatinine. The accuracy of this approach appears to be over 90%, and triages most patients with acute pancreatitis away from intensive care.

Unfortunately these and many other single and combined predictors of severity have an accuracy of only around 70%. This means that there is misclassification error of 30% that limits the value in predicting the severity of acute pancreatitis in individual patients. In the absence of any new biomarkers of ultimate disease severity, making better use of existing predictors through sequencing tests, combining tests or using artificial neural network methodologies has shown promise.

**Classification of the Severity of Acute Pancreatitis**

Accurately classifying or staging acute pancreatitis severity is important for clinical decision-making, communication, and enrollment into trials. The wide spectrum of pancreatitis severity has not been captured in the previous binary classifications (mild or severe). A four-category classification of severity (mild, moderate, severe, critical) (Table 33-8) has been developed on the principle of casual inference, derived by meta-analysis, refined by an international multidisciplinary process and independently validated. The key determinants of severity are local complications (absent, sterile or infected) and systemic complications (absent, transient organ failure, or persistent organ failure). The tracking of patient severity is important in delineating the clinical trajectory of a patient, and this classification of severity can be applied on a frequent basis. It can also be used in retrospect for audit purposes.

**Determining the Etiology**

A history of alcohol ingestion must be ascertained and preferably confirmed with blood ethanol levels. Gallstones should be investigated by ultrasonography. A gallstone etiology is more likely in females over the age of 50 with an elevation of alkaline phosphatase (>300 IU/L), alanine transferase (>100 IU/L) and amylase (>4000 IU/L). In the absence of gallstones and alcohol, a systematic approach to the identification of another factor will include taking a history for drug use, trauma, ERCP, infection, and measuring serum triglycerides, calcium, and others (Table 33-4).

**Fluid Resuscitation**

Fluid therapy to restore and maintain circulating blood volume is the most important intervention in the early management of acute pancreatitis. A recent systematic review has shown that

</tbody>
</table>
the evidence base for fluid therapy is scant, however. It is not known which fluid to give, how aggressively to administer it or what goal to use as a guide or to monitor the response to it. While there are proponents for aggressive fluid therapy and for specific resuscitation goals, it is probably best to resuscitate with a balanced crystalloid and to restore normal blood volume, blood pressure, and urine output. On the basis of recent data it appears that lactated Ringer’s solution may be superior to normal saline in reducing the systemic inflammatory response. Caution needs to be exercised in those with cardiac and renal disease and in the elderly.

**Nutritional Support**

In contrast to analgesia and fluid therapy there is a sound evidence base for nutritional support in acute pancreatitis. It is no longer acceptable to “rest the pancreas” by avoiding enteral nutrition, and parenteral nutrition should only be offered if the patient’s calculated nutritional requirements cannot be achieved by the enteral route. Enteral nutrition should be commenced after initial fluid resuscitation and within the first 24 hours of admission. It can be introduced through a nasogastric tube and increased in step-wise fashion over 2 to 3 days. The tube can be advanced to the jejunum, by endoscopy or fluoroscopy, if there is evidence of feeding intolerance. A delay in commencing enteral nutrition may contribute to the development of intestinal ileus and feeding intolerance. Aggressive early enteral feeding, particularly prior to adequate resuscitation, may put the patient at risk of nonocclusive mesenteric ischemia. There is no evidence to support the use of elemental or immune-enhancing formulas over standard polymeric formulas.

In predicted mild acute pancreatitis the transition from oral fluids to food is usually timed to when the patient’s abdominal pain has resolved, but the trend is toward allowing patients to resume intake ad libidum (i.e., patient controlled nutrition).

---

**Cross-sectional Imaging**

It may be necessary to perform a CT scan to diagnose acute pancreatitis in patients who are severely ill, or in those presenting with undifferentiated abdominal pain. But there is no advantage in using CT findings, or a “CT Severity Index,” over other methods in predicting the severity of acute pancreatitis. The primary purpose of cross-sectional imaging is the diagnosis of local complications, in particular the development and extent of pancreatic necrosis or the presence of different fluid collections. CT scanning is important to guide the insertion of percutaneous drains in the management of local complications. MR is superior to CT scanning in detecting any solid content within collections (Fig. 33-13). When bleeding is suspected in association with a local complication, an arterial phase CT scan (CTa) is useful in detecting a pseudoaneurysm, active bleeding, and/or hematoma.

**Therapeutic Endoscopic Retrograde Cholangiopancreatography (ERCP)**

Randomized trials have demonstrated that early ERCP (within 24 or 48 hours of admission) reduces complications, but not mortality, in patients with predicted severe gallstone-associated acute pancreatitis. The benefits of this invasive modality (release of the presumed impacted stone) may be offset, however, by the risks of the procedure, which include an increase in the severity of pancreatitis, bleeding, cholangitis, and duodenal perforation. More recent evidence has suggested that early ERCP confers no benefit in the absence of concomitant cholangitis, as the offending common duct stone usually passes before ERCP can be performed. If symptoms and chemical abnormalities persist or increase after initial presentation, magnetic resonance cholangio-pancreatography (MRCP) can detect a filling defect in the distal common bile duct, and may be used as prerequisite for attempted ERCP. Persistent cholestasis without cholangitis may require an ERCP but is rarely indicated in the acute setting.

Antibiotics

Although the use of broad-spectrum antibiotics to treat established infection in acute pancreatitis is a well-established practice, there has been considerable controversy surrounding the use of prophylactic antibiotics. The overuse of antibiotics has been associated with a documented rise in fungal infections and resistant organisms. Overall, it appears that the most recent and generally better designed studies do not support the use of prophylactic antibiotics to reduce the frequency of pancreatic infectious complications, surgical intervention, and death.

Managing Local Complications

Vigilance is required for the timely and accurate diagnosis of local complications. The decisions regarding how and when to intervene are often difficult. While guided by the information gained by cross-sectional imaging, the decision to intervene is based on the clinical status and trajectory of the patient and the poor response to maximal intensive care support. This means close monitoring of the patient by serial examination, supplemented by regular measurement of inflammatory markers (e.g., C reactive protein) and a pancreatic protocol CT scan if a local complication is suspected and intervention considered warranted. In practice, intervention is delayed in order to allow demarcation of necrosis, and a reduced risk of bleeding, disseminated infection and collateral damage to adjacent organs by an intervention (Fig. 33-14). Appreciation of this has resulted in a notable trend toward delayed intervention, now uncommon before 3 to 4 weeks from the onset of symptoms. An important emerging approach is the increasing use of percutaneous catheter drainage in patients with suspected infected complications. Fine needle aspiration is now rarely used to confirm infection because the insertion of a needle at the time of planned drainage allows confirmation of the suspected infection. Pre-emptive drainage with one or more catheters often produces improvement or stabilization of the patient’s overall clinical status. In this way drainage “buys time” and allows the lesion to become more walled off and safer to treat. Recent data suggest that primary percutaneous catheter drainage may be the only intervention required in a third to a half of patients and that this proportion might increase further if there were a standard protocol of regular catheter exchange, upsizing and irrigation.

A proportion of patients do however require further treatment when they fail to respond (the so-called “step up approach”) and there is a wide array of minimally invasive options to choose from (Fig. 33-15). These interventions can be classified on the basis of the method of visualization, route taken to the lesion and the purpose of the intervention. In practice the approach taken will depend on local expertise and equipment as well as

Figure 33-14. Operative view of infected acute pancreatitis. Peripancreatic infection, characterized by mucopurulent exudate, extends far beyond the boundaries of the pancreas in the retroperitoneum.

the location and type of the specific local complication. A large Dutch randomized trial has shown that open surgical techniques should only be considered in those who fail to respond to the step-up approach, that is prior percutaneous drainage and minimally invasive intervention.\(^7\) The exception is to be found in EUS guided internal drainage into stomach, duodenum, or transpapillary pancreatic duct stenting is the preferred approach.

### Managing Organ Failure

The specific management of multiple organ failure is beyond the scope of this chapter. The early identification of organ dysfunction and failure is important because it is a key determinant of severity and outcome and to facilitate the timely transfer of the patient to an intensive care unit to optimize management, provide organ support, and allow more intensive monitoring. The severity of organ failure can be scored (Table 33-6). The responsiveness of organ failure to resuscitation over the first 48 hours is an important prognostic clue; those that respond have transient organ failure and have a better outlook than those who do not respond and have persistent organ failure.\(^8\) Organ failure that develops later in the disease course is usually secondary to infection of a local complication and should be managed accordingly (Table 33-9).

Cholecystectomy

While it is widely accepted that cholecystectomy is essential to prevent gallstone pancreatitis recurrence, the timing of cholecystectomy is important. Index cholecystectomy, done in the same admission and prior to discharge, appears safe and can almost always be accomplished laparoscopically. But index cholecystectomy is not suitable for all patients, particularly some who have had local pancreatic complications which includes a large phlegmon which extends into the porta hepatitis. These patients may require an interval cholecystectomy after resolution of the inflammatory process. If surgery is required for the management of local complications, then a cholecystectomy is often performed at that time.

The management of acute pancreatitis remains a formidable challenge due to the variety and severity of many associated complications (Table 33-10), and continues to evolve. Although specific treatments for acute pancreatitis remain elusive, progress has been made in the management of pain, fluid resuscitation, antibiotic prophylaxis, enteral nutrition, therapeutic ERCP, and cholecystectomy. Progress has also been made in the intensive care management of systemic complications and in the development of less invasive interventions for the treatment of local complications, particularly infected pancreatic necrosis.

CHRONIC PANCREATITIS

Definition, Incidence, and Prevalence

Chronic pancreatitis is an incurable, chronic inflammatory condition that is multifactorial in its etiology, highly variable in its presentation, and a challenge to treat successfully. Autopsy studies indicate that evidence of chronic inflammation, such as fibrosis, duct ectasia, and acinar atrophy is seen in up to 5% of the population, although these data are difficult to interpret because many of these changes are also present in asymptomatic elderly patients. Population studies suggest a prevalence that ranges from 5 to 40 persons per 100,000 population, with considerable geographic variation. Differences in diagnostic criteria, regional nutrition, alcohol consumption, and medical access account for variations in the frequency of the diagnosis, but the overall incidence of the disease has risen progressively over the past 50 years.

Etiology

There are multiple etiologies of chronic pancreatitis, including genetic mutations, alcohol exposure, duct obstruction due to trauma, gallstones, and tumors, metabolic diseases such as hyperlipidemia and hyperparathyroidism, and auto-immune disease. In addition, nutritional causes include so-called “tropical pancreatitis,” which has been thought to result from ingestion of certain starchy foods. A significant number of patients have no discernible cause of the disease despite extensive testing, and are said to have idiopathic chronic pancreatitis.

Genetic Causes

In 1952, Comfort and Steinberg reported a kindred of “hereditary chronic relapsing pancreatitis” after treating the proband, a 24-year-old woman, at the Mayo Clinic. Subsequently, familial patterns of chronic, nonalcoholic pancreatitis have been described worldwide, and a familiar pattern has emerged. Typically, patients first present in childhood or adolescence with abdominal pain and are found to have chronic calcific pancreatitis on imaging studies. Progressive pancreatic dysfunction is common, and many patients present with symptoms due to pancreatic duct obstruction. The risk of subsequent carcinoma formation is increased, reaching a prevalence, in some series, of 40%, but the age of onset for carcinoma is typically >50 years old. The disorder is characterized by an autosomal dominant pattern of inheritance, with 80% penetrance and variable expression. The incidence is equal in both sexes.
Whitcomb and colleagues,\textsuperscript{85} and separately LeBodic and associates,\textsuperscript{86} performed gene linkage analysis and identified a linkage for hereditary pancreatitis to chromosome 7q35. Subsequently, the region was sequenced and revealed eight trypsinogen genes. Mutational analysis revealed a missense mutation resulting in an Arg to His substitution at position 117 of the cationic trypsinogen gene, or PRSS1, one of the primary sites for proteolysis of trypsin. This gain-of-function mutation results in an excess production of trypsin, which results in persistent and uncontrolled proteolytic activity and autodestruction within the pancreas.\textsuperscript{87} The position 117 mutation of PRSS1 and an additional mutation, now known collectively as the R122H and N291 mutations of PRSS1, account for about two-thirds of cases of hereditary pancreatitis. Recently, Masson and associates described a gain-of-function mutation in the anionic trypsinogen gene, PRSS2, that is also present in some cases.\textsuperscript{88}

Similarly, SPINK1, an inflammation-induced trypsin inhibitor secreted in acinar cells, has been found to have a role in hereditary pancreatitis. SPINK1 specifically inhibits trypsin action by competitively blocking the active site of the enzyme. Wit and colleagues investigated 96 unrelated children with chronic pancreatitis in France and found a variety of SPINK1 mutations in 23% of the patients.\textsuperscript{89} Several studies have now confirmed an association of loss-of-function SPINK1 mutations with familial and idiopathic forms of chronic pancreatitis, as well as so-called tropical pancreatitis.\textsuperscript{90, 91} SPINK1 mutations are common in the general population as well, and the frequency of these mutations varies in different cohorts of idiopathic chronic pancreatitis, from 6.4% in France\textsuperscript{92} to 25.8% in the United States.\textsuperscript{93} Thus, hereditary pancreatitis results from one or more mutational defects that incapacitate an auto-protective process that normally prevents proteolysis within the pancreas.

Cystic fibrosis, originally termed cystic fibrosis of the pancreas, results from a variety of mutations of the cystic fibrosis transmembrane receptor (CFTR). The CFTR is present in pancreatic duct cells, and controls the amount of chloride and bicarbonate secreted into the normally alkaline pancreatic juice. The CFTR gene contains over 4300 nucleotides, divided into 24 exons, which encode a 1480-amino acid protein. Over 1000 polymorphisms have been reported, and many are common.\textsuperscript{94} The CFTR mutation associated with the classic pulmonary disease, F508, is rarely observed in chronic pancreatitis. But other CFTR mutations have been noted to be associated with chronic idiopathic pancreatitis and auto-immune pancreatitis in which the pulmonary, intestinal, and cutaneous manifestations of the disease are silent.\textsuperscript{95}

Many studies have been undertaken to determine whether specific genetic abnormalities are associated with alcoholic chronic pancreatitis, and which might confer susceptibility to the disease. A 5.8% rate of SPINK1 mutations in patients with alcoholic pancreatitis has been shown, compared to a 0.8% rate in the control population, and studies of the known mutations of the CFTR gene have failed to demonstrate a strong association with alcoholic chronic pancreatitis.\textsuperscript{96}

In 2012, a landmark study by Whitcomb and associates demonstrated a likely genetic cause of the predisposition to alcohol-induced chronic pancreatitis in men.\textsuperscript{97} In a genome-wide association study of more than 2000 patients, these researchers discovered that a common DNA variant on the X chromosome is present in 26% of men without pancreatitis, but jumps to nearly 50% of men diagnosed with alcoholic pancreatitis. The variant involves the claudin 2 (CLDN2) gene, which encodes a tight junction protein normally present in ductal cells. In cases of chronic pancreatitis, the CLDN2 protein is abnormally expressed in acinar cells, and may alter the secretory dynamics of enzyme release. The abnormality does not appear to cause pancreatitis but if pancreatitis occurs for any reason in a person with the CLDN2 variant, it is more likely that the person will develop chronic pancreatitis; the risk is increased even further among alcohol users. Only 10% of women have the X chromosome-linked variant on both X chromosomes, and most women with the CLDN2 variant on one X chromosome appear to be protected from alcoholic chronic pancreatitis by the other X chromosome, if it is normal. Men, with only one X chromosome, have no protection if they inherit a CLDN2 mutation. This helps to explain the high prevalence of alcoholic chronic pancreatitis among men, although the mechanism remains unclear. This study does not demonstrate a genetic cause for all cases of alcohol-related chronic pancreatitis, but shows that a genetic element contributes to many patients with the disease (Fig. 33-16).

Alcohol

In 1878, Friedreich proposed that “a general chronic interstitial pancreatitis may result from excessive alcoholism (drunkard’s pancreas).”\textsuperscript{98} Since that observation, numerous studies have shown that a causal relationship exists between alcohol and chronic pancreatitis, but the prevalence of alcohol as the etiology of the disease in Western countries ranges widely, from 38% to 94%\textsuperscript{99}(Fig. 33-17).

There is a linear relationship between exposure to alcohol and the development of chronic pancreatitis.\textsuperscript{86} The risk of disease is present in patients with even a low or occasional exposure to alcohol (1 to 20 g/d), perhaps due to the CLDN2 gene mutation described above, so there is no threshold level of alcohol exposure below which there is no risk of developing chronic pancreatitis. Furthermore, although the risk of disease is dose related, and highest in heavy (>150 g/d) drinkers, the prevalence of chronic pancreatitis among confirmed alcohol abusers is only 5% to 15%.\textsuperscript{99} However, the duration of alcohol consumption is definitely associated with the development of pancreatic disease. The onset of disease typically occurs between ages 35 to 40 years, after 16 to 20 years of heavy alcohol consumption. Recurrent episodes of acute pancreatitis are typically followed by chronic symptoms after 4 or 5 years.\textsuperscript{100}

Although the pattern of disease presentation is well known in those alcohol users who develop pancreatic disease, the pathophysiology of alcohol-induced pancreatic disease is still an area of active investigation. In their 1946 classic study, Comfort, Gambrill, and Baggenstoss proposed that chronic pancreatitis was the result of multiple episodes of acute inflammation, with residual and progressively increasing chronic inflammation.\textsuperscript{101} Subsequently, other investigators proposed that initial acute inflammation was not necessarily linked to chronic changes in the pancreas,\textsuperscript{102} and Kondo and associates showed that other, additional factors were necessary for repeated exposure to alcohol to cause chronic pancreatitis.\textsuperscript{103} Regardless of the requirement for other predisposing or facilitative factors, the concept that multiple episodes (or a prolonged course) of pancreatic injury ultimately leads to chronic disease is widely accepted as the pathophysiological sequence\textsuperscript{104} (Fig. 33-18).

Although direct alcohol exposure to the pancreatic ductal system, or elevated levels of alcohol in the bloodstream, has

premature activation of trypsinogen. Mutations in the cystic fibrosis
transmembrane receptor (CFTR) results in abnormal expression in acinar cells,
instead of its normal location between duct cells, and is associated
with the accelerated development of chronic pancreatitis in alcohol
subjects. Cationic and anionic trypsinogen are normally active in the duodenum by enterokinase (EK). Premature activation of the trypsin in the acinar cell
leads to zymogen activation, local cellular injury, and inflammation.
Mutations in the cystic fibrosis transmembrane receptor CFTR result in premature activation of trypsinogen. Mutations in the cystic fibrosis
transmembrane receptor CFTR results in trypsinogen stasis within the ducts due to insufficient secretion by duct cells. A Mutation in
claudin-2 (CLDN2) results in abnormal expression in acinar cells, instead of its normal location between duct cells, and is associated
with the accelerated development of chronic pancreatitis in alcohol
abusers. (Adapted with permission from Macmillan Publishers, Ltd.
Whitcomb DC et al: Common genetic variants in the CLDN2 and
PRSS1-PRSS2 loci alter risk for alcohol-related and sporadic

been shown to alter the integrity and function of pancreatic
ducts and acini directly. Most investigators believe that alcohol
metabolites such as acetaldehyde, combined with oxidant
injury, result in local parenchymal injury that is preferentially
targeted to the pancreas in predisposed individuals. Repeated
or severe episodes of toxin-induced injury activate a cascade
of cytokines, which, in turn, induces pancreatic stellate cells
(PSCs) to produce collagen and cause fibrosis (Fig. 33-19).
It remains to be determined whether alcohol sensitizes the
pancreas of susceptible individuals to another cause of acute
inflammation, or whether genetic or other factors predispose to
direct alcohol-related injury.

Alcohol may interfere with the intracellular transport and
discharge of digestive enzymes, and may contribute to the colo-

Figure 33-16. Schematic model of genetic causes of chronic pancreatitis. A pancreatic acinus is portrayed showing the pathway for digestive enzymes (zymogens) to be secreted by the acinar cell into the ductal system where water, sodium, and bicarbonate are secreted by the duct and centroacinar (CA) cells. Mutations in at least five genes have been identified as risk factors for chronic pancreatitis: gain-of-function mutations in the cationic trypsinogen genes (PRSS1, PRSS2) cause hereditary pancreatitis. Cationic and anionic trypsinogen are normally active in the duodenum by enterokinase (EK). Premature activation of the trypsin in the acinar cell leads to zymogen activation, local cellular injury, and inflammation. Mutations of the trypsin inhibitors SPINK1 or chymotrypsin C (CTRCC), or of the calcium sensing receptor CASR, result in premature activation of trypsinogen. Mutations in the cystic fibrosis transmembrane receptor CFTR result in trypsinogen stasis within the ducts due to insufficient secretion by duct cells. A Mutation in claudin-2 (CLDN2) results in abnormal expression in acinar cells, instead of its normal location between duct cells, and is associated with the accelerated development of chronic pancreatitis in alcohol abusers. (Adapted with permission from Macmillan Publishers, Ltd. Whitcomb DC et al: Common genetic variants in the CLDN2 and PRSS1-PRSS2 loci alter risk for alcohol-related and sporadic pancreatitis. by about 20 years. Smoking therefore appears to be an independent risk factor for the late complications of alcoholic pancreatitis, if not an early cofactor for the development of fibrosis.

**Hyperparathyroidism**
Hypercalcemia is a known cause of pancreatic hypersecretion, and chronic hypercalcemia caused by untreated hyperparathyroidism is associated with chronic calcific pancreatitis. Hypercalcemia is also a stimulus for pancreatic calcium secretion, which contributes to calculus formation and obstructive pancreatitis. The treatment is correction of the hyperparathyroidism and assessment of any additional endocrinopathies.

**Hyperlipidemia**
In addition to the risk of acute pancreatitis, hyperlipidemia and hypertriglyceridemia predispose women to chronic pancreatitis when they receive estrogen replacement therapy. Fastig triglyceride levels <300 mg/dL are below the threshold for this to occur, and the mechanism of estrogen potentiation of hyperlipidemia-induced chronic pancreatitis is unknown. It is assumed that chronic changes occur after repeated subclinical episodes of acute inflammation. Aggressive therapy of hyperlipidemia is therefore important in peri- or postmenopausal patients who are candidates for estrogen therapy.

**Classification**
A major impediment to a better understanding of the etiology, frequency and severity of chronic pancreatitis has been the difficulty with which investigators and clinicians have struggled to identify a useful classification system. Multiple classification systems have been proposed. The TIGAR-O scheme categorizes chronic pancreatitis according to risk factors and etiologies, such as a) toxic-metabolic, b) idiopathic, c) genetic, d) auto-immune, e) recurrent and severe acute pancreatitis, or f) obstructive. A recent classification system based on histopathology as well as etiology, as delineated by Singer and Chari, is shown in Table 33-11.

Wirsung’s duct (Fig. 33-20). However, the classic picture of obstructive pancreatopathy with a dilated dorsal duct is unusual in pancreas divisum, so a decompressive operation or a lesser papilla sphincteroplasty is frequently not feasible or unsuccessful. Endoscopic stenting through the lesser papilla may result in temporary relief of symptoms, and this response would increase the possibility that a permanent surgical or endoscopic intervention will be successful. Although some authors emphasize the pathologic implications of pancreas divisum, others express skepticism that it represents a true risk to pancreatic secretory capacity or contributes to the development of chronic pancreatitis.

A recent French study reveals that pancreas divisum is equally prevalent among patients with idiopathic chronic pancreatitis and normal controls (7%), and is minimally increased in patients with PRSS1 and SPINK1 mutations. It is accompanied by CFTR mutations in 47% of patients, however, suggesting that the presence of pancreas divisum together with mutational events may increase the susceptibility to pancreatitis.

Chronic Inflammatory Pancreatitis

Chronic inflammatory pancreatitis is characterized by diffuse fibrosis and a loss of acinar elements with a predominant monocellular cell infiltration throughout the gland.

A variant of chronic pancreatitis is a nonobstructive, diffusely infiltrative disease associated with fibrosis, a monocellular cell (lymphocyte, plasma cell, or eosinophil) infiltrate, and an increased titer of one or more autoantibodies. This type, referred to as autoimmune pancreatitis (AIP), is associated with a variety of illnesses with suspected or proven autoimmune etiology, such as Sjögren’s syndrome, rheumatoid arthritis, and type I diabetes mellitus. AIP has been characterized as either type I, with accompanying systemic or multigorgan dysfunction, or type II, which is restricted to the pancreas.

Compressive stenosis of the intrapancreatic portion of the common bile duct is frequently seen in both types of AIP, along with symptoms of obstructive jaundice. Increased levels of serum β-globulin or immunoglobulin G4 are also present. Steroid therapy is uniformly successful in ameliorating the disease, including any associated bile duct compression. CFTR mutations which result in dislocation of the transmembrane protein have been found in AIP, and steroid therapy results in a normalization of the CFTR localization, and a resumption of normal chloride and bicarbonate secretion. The differential diagnosis includes lymphoma, plasmacytoma (“pseudotumor” of the pancreas), and diffuse infiltrative carcinoma. Although the diagnosis is confirmed on pancreatic biopsy, presumptive treatment with steroids is usually undertaken, especially when clinical and laboratory findings, such as an elevation in IgG4 levels, support the diagnosis. Failure to obtain a cytologic specimen may lead to an unnecessary resectional procedure, and an untreated inflammatory component may cause sclerosis of the extrahepatic or intrahepatic bile ducts, with eventual liver failure.

Tropical (Nutritional) Pancreatitis

Chronic pancreatitis is highly prevalent among adolescents and young adults in Indonesia, southern India, and tropical Africa. Abdominal pain develops in adolescence, followed by the development of a brittle form of pancreatogenic diabetes. Parenchymal and intraductal calcifications are seen, and the pancreatic duct stones may be quite large. Many of the patients appear malnourished, some present with extreme emaciation, and a characteristic cyanotic coloration of the lips may be seen. In addition to protein-caloric malnutrition, toxic products of some indigenous foodstuffs have also been thought to contribute to the disease. Because of the geographic concentration of this early-onset form of chronic pancreatitis, it has been termed “tropical pancreatitis,” although the exact etiology remains unclear.

Clinically, tropical pancreatitis presents much like hereditary pancreatitis, and a familial pattern among cases is not unusual.
SPINK1 mutations have been documented in 20% to 55% of patients with tropical pancreatitis, and CFTR mutations have been reported as well. The accelerated deterioration of endocrine and exocrine function, the chronic pain due to obstructive disease, and the recurrence of symptoms despite decompressive procedures characterize the course of disease. As immigrants from the tropical regions increasingly find their way to all parts of the world, an awareness of this severe form of chronic pancreatitis is helpful for those who treat patients with pancreatic disease.

Asymptomatic Pancreatic Fibrosis
Pancreatic fibrosis is seen in some asymptomatic elderly patients, in tropical populations, or in asymptomatic alcohol users. There is diffuse perilobular fibrosis and a loss of acinar cell mass, but without a main ductular component.

A shortcoming of these clinical classification systems is the lack of histologic criteria of chronic inflammation due to the usual absence of a biopsy specimen. The differentiation of recurrent acute pancreatitis from chronic pancreatitis with exacerbations of pain can be difficult to establish and is not facilitated by the current system. Similarly, cystic fibrosis is known to cause fibrosis and acinar dysfunction but is not included in the classification despite increasing evidence for its possible role in idiopathic chronic pancreatitis. Therefore, further refinements in the classification system for chronic pancreatitis are needed to allow a better prediction of its clinical course and a more accurate diagnosis of a likely etiologic agent.

Idiopathic Pancreatitis
When a definable cause for chronic pancreatitis is lacking, the term idiopathic is used to categorize the illness. Classically, the idiopathic group includes young adults and adolescents who lack a family history of pancreatitis but who may represent individuals with spontaneous gene mutations encoding regulatory proteins in the pancreas. A variable percentage of SPINK1 and CFTR mutations have been described in various studies. In addition, the idiopathic group has included a large number of older patients for whom no obvious cause of recurrent or chronic pancreatitis can be found. However, because the prevalence of biliary calculi increases steadily with age, it is not surprising that, as methods of biliary stone detection have improved, many elderly “idiopathic” pancreatitis patients are found to have biliary tract disease.

As previously noted, an increasing number of mutations of the SPINK1 and CFTR genes have been identified in association with various forms of chronic pancreatitis. However, the role of genetic analysis in the management of these patients remains unclear, as guidelines have yet to be developed to allow physicians to use the data consistently. The clinical management of patients who harbor a minor CFTR mutation and chronic pancreatitis, for example, is still dictated by the clinical manifestations of the pancreatitis.

Pathology
Histology. In early chronic pancreatitis, the histologic changes are unevenly distributed and are characterized by induration, nodular scarring, and lobular regions of fibrosis (Fig. 33-21). As the disease progresses, there is a loss of normal lobulation, with thicker sheets of fibrosis surrounding a reduced acinar cell mass, and dilatation of ductular structures (Fig. 33-22). The ductular epithelium is usually atypical and may display features of dysplasia, as evidenced by cuboidal cells with hyperplastic features, accompanied by areas of mononuclear cell infiltrates or patchy areas of necrosis. Cystic changes may be seen, but areas of relatively intact acinar elements and normal-appearing islets persist. In severe chronic pancreatitis, there is considerable replacement of acinar tissue by broad, coalescing areas of fibrosis, and the islet size and number are reduced (Fig. 33-23). Small arteries appear thickened and neural trunks become prominent.

Tropical pancreatitis and hereditary pancreatitis are histologically indistinguishable from chronic alcoholic pancreatitis. In obstructive chronic pancreatitis, calculi are absent, although periarcinal fibrosis and dilated ductular structures are prominent. In pancreatic lobular fibrosis seen in elderly subjects, small ducts are dilated, sometimes with small calculi trapped within. Hypertrophy of ductular epithelia is thought to cause this small-duct disease, which is accompanied by perilobular fibrosis.

Fibrosis. A common feature of all forms of chronic pancreatitis is the perilobular fibrosis that forms surrounding individual acini, then propagates to surround small lobules, and eventually coalesces to replace larger areas of acinar tissue. The pathogenesis of this process involves the activation of pancreatic
stellate cells (PSCs) that are found adjacent to acini and small arteries. The extended cytoplasmic processes of PSCs encircle the acini but appear quiescent in the normal gland, where they contain lipid vacuoles and cytoskeletal proteins. In response to pancreatic injury, the PSCs become activated and proliferate (similarly to hepatic stellate cells), lose their lipid vesicles, and transform into myofibroblast-like cells. These cells respond to proliferative factors such as transforming growth factor beta, platelet-derived growth factor, and proinflammatory cytokines and synthesize and secrete type I and III collagen and fibronectin. Studies indicate that vitamin A metabolites, similar to those present in quiescent PSCs, can inhibit the collagen production of activated cultured PSCs. This raises the possibility that early intervention may be possible to interrupt or prevent the fibrosis resulting from ongoing activation of PSCs.

The overall pathogenic sequence proposed by Schneider and Whitcomb whereby alcohol induces acute pancreatitis and, with ongoing exposure, promotes the development of chronic fibrosis, is summarized in Fig. 33-19. PSCs surrounding the acini are activated in acute pancreatitis but may be inactivated by anti-inflammatory cytokines and, in the absence of further injury, may revert to a quiescent state. The role of proinflammatory macrophages, cytokines, and PSCs in models of acute and chronic pancreatitis represents an important area of current research.

**Stone Formation.** Pancreatic stones are composed largely of calcium carbonate crystals trapped in a matrix of fibrillar and other material. The fibrillar center of most stones contains no calcium but rather a mixture of other metals. This suggests that stones form from an initial noncalcified protein precipitate, which serves as a focus for layered calcium carbonate precipitation. The same low-molecular-weight protein is present in stones and protein plugs and was initially named pancreatic stone protein, or PSP. PSP was found to be a potent inhibitor of calcium carbonate crystal growth and has subsequently been renamed lithostathine. Independently, a 15-kDa fibrillar protein isolated from the pancreas was named pancreatic thread protein, and it has been shown to be homologous with lithostathine. Finally, a protein product of the reg gene, so named because it is expressed in association with regenerating islets in models of pancreatic injury, was isolated and called reg protein, and was subsequently found to be homologous with lithostathine. No overall homology has been found between lithostathine and other pancreatic proteins. The PSP/pancreatic thread protein/reg/lithostathine gene encodes for a 166-amino acid product that undergoes post-translational modification to produce isoforms present in pancreatic juice. The protein is expressed in all rodents and mammals, both in the pancreas as well as in brain tissue, where it is found in particularly high concentrations in pyramidal neurons in Alzheimer’s disease and Down syndrome. It is also found in the renal tubules, which is consistent with its biologic action of preventing calcium carbonate precipitation.

Calcium and bicarbonate ions are normally present in pancreatic juice in high concentrations, and the solubility product of calcium carbonate is greatly exceeded under normal conditions. Microcrystals of calcium carbonate can be seen in normal pancreatic juice but are usually clinically silent. Lithostathine is a potent inhibitor of calcium carbonate crystal formation, at a concentration of only 0.1 μmol/L. However, lithostathine concentrations in normal pancreatic juice are in the range of 20 to 25 μmol/L, so a constant suppression of calcium carbonate crystal formation is present in the normal pancreas.

In alcoholics and in patients with alcoholic chronic pancreatitis, lithostathine expression and secretion are dramatically inhibited (Fig. 33-24). In addition, elevated levels of precipitated lithostathine in the duct fluid in chronic pancreatitis patients suggests that the availability of the protein may be further reduced by the action of increased proteases and other proteins present in the duct fluid of alcoholic patients. Increased pancreatic juice protein levels in alcoholic men are reversible by abstinence from alcohol, so the availability and effectiveness of lithostathine may be restored in patients with early-stage disease by timely intervention. Nevertheless, calcific stone formation represents an advanced stage of disease, which can further promote injury or symptoms due to mechanical damage to duct epithelium or obstruction of the ductular network.

**Duct Distortion.** Although calcific stone disease is normally a marker for an advanced stage of disease, parenchymal and...
ductular calcifications do not always correlate with symptoms. Obstructing main duct stones are commonly observed and are thought to be an indication for endoscopic or surgical removal. The ball-valve effect of a stone in a secreting system produces inevitable episodes of duct obstruction, usually accompanied by pain. But some patients with complete duct obstruction have prolonged periods of painlessness. Ductular hypertension has been documented in patients with proximal stenosis of the main pancreatic duct, and prolonged ductular distention after secretin administration is taken as a sign of ductular obstruction.\textsuperscript{141} Although calculus disease and duct enlargement appear together as late stages of chronic pancreatitis, controversy persists over whether they are associated, are independent events, or are causally related.

**Radiology.** Radiologic imaging of chronic pancreatitis assists in four areas: (a) diagnosis, (b) the evaluation of severity of disease, (c) detection of complications, and (d) assistance in determining treatment options.\textsuperscript{142} With the advent of cross-sectional imaging techniques such as CT and magnetic resonance imaging (MRI), the contour, content, ductal pattern, calcifications, calculi, and cystic disease of the pancreas are all readily discernible. Transabdominal ultrasonography is frequently used as a screening method for patients with abdominal symptoms or trauma, and the extension of ultrasonic imaging to include endoscopic ultrasound (EUS) and laparoscopic US have resulted in the highest-resolution images that are capable of detecting very small (<1 cm) abnormalities in the pancreas. EUS is now frequently used as a preliminary step in the evaluation of patients with pancreatic disease, and magnetic resonance cholangiopancreatography (MRCP) is increasingly being used to select patients who are candidates for the most invasive imaging method, ERCP. The staging of disease is important in the care of patients, and a combination of imaging methods is usually used (Table 33-12).

Ultrasonography is frequently used as an initial imaging method in patients with abdominal symptoms, and changes consistent with pancreatic duct dilatation, intraductal filling defects, cystic changes, and a heterogeneous texture are seen in chronic pancreatitis (Fig. 33-25). The sensitivity of transabdominal ultrasonography ranges from 48% to 96%, and is operator dependent.\textsuperscript{143} However, the contour, texture, and ductal pattern are usually quite discernible, and it is a reliable method for periodic re-examination to determine the efficacy of treatment. EUS has heavily impacted the evaluation and management of patients with chronic pancreatitis. Although it is more operator dependent and less widely available than transabdominal ultrasonography, EUS provides not only imaging capability but adds the capacity to obtain cytologic and chemical samples of tissue and fluid aspirated with linear array monitoring (Fig. 33-26). EUS images obtained through a high-frequency (7.5- to 12.5-mHz) transducer are able to evaluate subtle changes in 2- to 3-mm structures within the pancreas and can detect indolent neoplasms in the setting of chronic inflammation. Small intraductal lesions, intraductal mucus, cystic lesions, and subtle ductular abnormalities are recognizable by EUS (Table 33-13). This allows ERCP to be reserved for these patients who require therapeutic maneuvers, or for the evaluation of more complex problems. EUS is comparable to ERCP in the detection of advanced changes in chronic pancreatitis and may be more sensitive than ERCP in the detection of mild disease.\textsuperscript{144}

CT scanning has affected the diagnosis of pancreatic disease more broadly than any other method. With the advent of faster helical CT scanning and CT angiography, visualization of the nature, extent, location, and relative relationships of pancreatic structures and lesions is possible with great clarity. Duct dilatation, calculus disease, cystic changes, inflammatory events, and anomalies are all detectable with a resolution of 3 to 4 mm (Fig. 33-27). CT scanning has a false-negative rate of <10% for chronic pancreatitis, but early or mild chronic

disease may go undetected by CT imaging. The earliest changes are dilatation of secondary ducts and heterogeneous parenchymal changes, which are detectable by EUS and ERCP. Another drawback of CT scanning is its lower sensitivity for detecting small neoplasms, which are seen with increased frequency in chronic pancreatitis and may be invisible to all modalities except EUS.

An MRI, in both the cross-sectional mode and the coronally oriented heavily weighted T2 or high spin ratio imaging (MRCP) that can disclose fluid-filled ducts and cystic lesions, has added greatly to the imaging options for chronic pancreatitis (Fig. 33-28). The resolution of cross-sectional MRI scanning is now approaching that of CT scanning, although the availability of MRI scanners and the complexity of the images produced have limited their large-scale use for routine imaging of the pancreas. MRCP has been shown to be an effective screening technique for disclosing ductal abnormalities that correlates closely with the contrast-filled ducts imaged by ERCP. The advantages of MRCP include its noninvasive methodology and its ability to image obstructed ducts that are not opacified by ERCP injection. It is therefore a useful screening study to detect duct abnormalities and to confirm the need for interventional procedures. Oral, IV, and intraductal contrast are unnecessary for MRCP, and its lack of ionizing radiation makes this the safest method to image the ductal system in high-risk patients.

For the diagnosis and staging of chronic pancreatitis, ERCP is considered to be the gold standard. It also serves as a vehicle that enables other diagnostic and therapeutic maneuvers, such as...

biopsy or brushing for cytology, or the use of stents to relieve obstruction or drain a pseudocyst (Fig. 33-29). Unfortunately, ERCP also carries a risk of procedure-induced pancreatitis that occurs in approximately 5% of patients. Patients at increased risk include those with sphincter of Oddi dysfunction and those with a previous history of post-ERCP pancreatitis. Post-ERCP pancreatitis occurs after uncomplicated procedures, as well as after those that require prolonged manipulation. Severe pancreatitis and deaths have occurred after ERCP. It should be reserved for patients in whom the diagnosis is uncertain despite the use of other imaging methods, or in whom a diagnostic or therapeutic maneuver is specifically indicated.

Presentation, Natural History, and Complications

Presenting Signs and Symptoms. Pain is the most common symptom of chronic pancreatitis. It is usually midepigastric in location but may localize or involve either the left or right upper quadrant of the abdomen. Occasionally, it is perceived in the lower midabdomen but is frequently described as penetrating through to the back (Fig. 33-30). The pain is typically steady and boring, but not colicky. It persists for hours or days and may be chronic with exacerbations caused by eating or drinking alcohol. Chronic alcoholics also describe a steady, constant pain that is temporarily relieved by alcohol, followed by a more severe recurrence hours later.

Patients with chronic pancreatic pain typically flex their abdomen and either sit or lie with their hips flexed, or lie on their side in a fetal position. Unlike ureteral stone pain or biliary colic, the pain causes the patient to be still. Nausea or vomiting may accompany the pain, but anorexia is the most common associated symptom.

Pain from chronic pancreatitis has been ascribed to three possible etiologies. Ductal hypertension, due to strictures or stones, may predispose to pain that is initiated or exacerbated by eating. Chronic pain without exacerbation may be related to parenchymal disease or retroperitoneal inflammation with persistent neural involvement. Acute exacerbations of pain in the setting of chronic pain may be due to acute increases in duct pressure or recurrent episodes of acute inflammation in the setting of chronic parenchymal disease. Nealon and Matin have described these various pain syndromes as being predictive of the response to various surgical procedures. Pain that is found in association with ductal hypertension is most readily relieved by pancreatic duct decompression, through endoscopic stenting or surgical decompression.

The surgical relief of pain due to obstructive pancreatopathy may be dependent on the degree of underlying fibrosis rather than the presence of ductal obstruction, per se, according to a recent study from Johns Hopkins by Cooper et al. About 35 patients with chronic pain associated with evidence of duct obstruction were treated with Local Resection of the pancreatic head and Longitudinal Pancreatico-Jejunostomy (LR-LPJ), or Frey

Figure 33-29. Pancreatic duct stenting. At endoscopic retrograde cholangiopancreatography, a stent is placed in the proximal pancreatic duct to relieve obstruction and reduce symptoms of pain. Pancreatic duct stents are left in place for only a limited time to avoid further inflammation.

procedure, and the degree of pain resolution after surgery was compared to the degree of underlying parenchymal fibrosis. After a follow-up that averaged 22 months, patients with more than 80% fibrosis had 100% pain relief, whereas only 60% patients with less than 10% fibrosis experienced substantial or complete pain relief (Fig. 33-31). These findings suggest that minimal fibrosis, or "minimal change chronic pancreatitis," may produce chronic pain due to extrapancreatic or "peri-pancreatic" inflammatory events which are not ameliorated by decompression.

The pain of chronic pancreatitis may decrease or disappear completely over a period of years, as symptoms of exocrine and endocrine deficiency become apparent.\textsuperscript{14} This is referred to as burned out pancreatitis and correlates with the progression of disease from a mild or moderate stage to severe destruction of the pancreas. Although this evolution of painful to nonpainful disease is sometimes used as a justification to avoid intervention in painful chronic pancreatitis, noninterventional approaches to the treatment of chronic pancreatitis are inevitably accompanied by the development of narcotic addiction, inability to work, and the sequelae of chronic illness.

Although increased ductal pressure, and therefore parenchymal pressure, is thought to be the cause of pain in chronic obstructive pancreatitis, the role of chronic inflammation per se, and the development of actual nerve damage in the diseased gland, are also thought to contribute to pain.\textsuperscript{14} Chronic inflammation results in the infiltration of tissue by macrophages, which secrete prostaglandins and other nociceptive agents that cause chronic stimulation of afferent neural fibers. Inflammation damage to the perineurial layers surrounding the unmyelinated pancreatic nerves and a focal infiltration of inflammatory cells around nerves suggest that neural fibers are a target for the cellular response to inflammation in the pancreas.\textsuperscript{138}

Strategies to relieve pain are therefore based on three approaches: (a) reducing secretion and/or decompress the secretory compartment, (b) resecting the focus of chronic inflammatory change, or (c) interrupting the transmission of afferent neural impulses through neural ablative procedures. A trial of antisecretory therapy or endoscopic duct drainage may select those patients who will benefit preferentially from a decompressive procedure.

**Malabsorption and Weight Loss.** When pancreatic exocrine capacity falls below 10% of normal, diarrhea and steatorrhea develop\textsuperscript{131} (Fig. 33-32). Patients describe a bulky, foul-smelling, loose (but not watery) stool that may be pale in color and float on the surface of toilet water. Frequently, patients will describe a greasy or oily appearance to the stool, or may describe an "oil slick" on the water’s surface. In severe steatorrhea, an orange, oily stool is often reported. As exocrine deficiency increases, symptoms of steatorrhea are often accompanied by weight loss. Patients may describe a good appetite despite weight loss, or diminished food intake due to abdominal pain.

In severe symptomatic chronic pancreatitis, anorexia or nausea may occur with or separate from abdominal pain. The combination of decreased food intake and malabsorption of nutrients usually results in chronic weight loss. As a result, many patients with severe chronic pancreatitis are below ideal body weight.

Lipase deficiency tends to manifest itself before trypsin deficiency, so the presence of steatorrhea may be the first functional sign of pancreatic insufficiency.\textsuperscript{132} As pancreatic exocrine function deteriorates further, the secretion of bicarbonate into the duodenum is reduced, which causes duodenal acidification and further impairs nutrient absorption.\textsuperscript{143} Pancreatic exocrine insufficiency is frequently asymptomatic, however, and pancreatic exocrine function is difficult to measure, so a diagnosis of chronic pancreatitis is sufficient to justify a trial of pancreatic enzyme supplements. Each meal should be followed by 90,000 United States Pharmacopeia units of lipase, and the metabolic and symptomatic status of the patients should be followed.\textsuperscript{144}

**Pancreatogenic Diabetes.** The islets comprise only 2% of the mass of the pancreas, but they are preferentially conserved when pancreatic inflammation occurs. In chronic pancreatitis, acinar tissue loss and replacement by fibrosis is greater than the degree of loss of islet tissue, although islets are typically smaller than normal and may be isolated from their surrounding vascular network by the fibrosis. With progressive destruction of the gland, endocrine insufficiency commonly occurs. Frank diabetes is seen initially in about 20% of patients with chronic pancreatitis, and impaired glucose metabolism can be detected in up to 70% of patients. In a study of 500 patients with predominantly

alcoholic chronic pancreatitis, diabetes developed in 83% within 25 years of the clinical onset of chronic pancreatitis, and more than half of the diabetic patients required insulin treatment.\(^{155}\) Ketoadosis and diabetic nephropathy are relatively uncommon in pancreatogenic diabetes (Table 33-3), but retinopathy and neuropathy are seen to occur with a similar frequency as in type 1 and type 2 diabetes.\(^{156}\)

Pancreatogenic diabetes is most common in cases of chronic pancreatitis, and is often seen after surgical resection for benign or malignant disease.\(^{157,158}\) (Fig. 33-33). Distal pancreatectomy and Whipple procedures have a higher incidence of diabetes than do drainage procedures, and the severity of diabetes is usually worse after subtotal or total pancreatectomy. Pancreatogenic, or type 3c diabetes (T3cDM), is seen in cystic fibrosis, in association with pancreatic cancer, and in cases of severe hemachromatosis.\(^{159}\)

The etiology and pathophysiology of pancreatogenic diabetes is distinct from that of either autoimmune (type 1) or obesity-related (type 2) diabetes. In type 3c diabetes, the loss of functioning pancreatic tissue by disease or surgical removal results in a global deficiency of all three glucoregulatory islet cell hormones: insulin, glucagon, and PP. In addition, there is a paradoxical combination of enhanced peripheral sensitivity to insulin and decreased hepatic sensitivity to insulin.\(^{160}\) As a result, insulin therapy is frequently difficult; patients are hyperglycemic when insulin replacement is insufficient (due to unsuppressed hepatic glucose production) or hypoglycemic when insulin replacement is barely excessive (due to enhanced peripheral insulin sensitivity and a deficiency of pancreatic glucagon secretion to counteract the hypoglycemia). This form of diabetes is referred to as brittle diabetes and requires special attention.

PP deficiency correlates with the severity of chronic pancreatitis, and impairments in the hepatic action of insulin are reversed in PP-deficient chronic pancreatitis patients by administration of PP.\(^{161}\) In addition, a recent study of type 1 and type 3c diabetic patients on insulin pump therapy revealed that the addition of a continuous subcutaneous infusion of PP reduced the insulin requirements needed for glycemic control.\(^{162}\) This suggests that the treatment of pancreatogenic diabetes may be improved by the use of a clinically suitable PP analog or PP receptor agonist.

**Laboratory Studies.** The diagnosis of chronic pancreatitis depends on the clinical presentation, a limited number of indirect measurements that correlate with pancreatic function, and selected imaging studies (Table 33-14). The direct measurement of pancreatic enzymes (e.g., lipase and amylase) by blood test is highly sensitive and fairly specific in acute pancreatitis but is seldom helpful in the diagnosis of chronic pancreatitis. The pancreatic endocrine product that correlates most strongly with chronic pancreatitis is the PP response to a test meal (Fig. 33-34). Severe chronic pancreatitis is associated with a blunted or absent PP response to feeding but, as with many other tests, a normal PP response does not rule out the presence of early disease.\(^{14}\)

The measurement of pancreatic exocrine secretion requires aspiration of pancreatic juice from the duodenum after nutrient (Lundh test meal) or hormonal (CCK or secretin) stimulation.\(^{163,164}\) Direct aspiration of pancreatic juice by endoscopic cannulation of the duct is performed in some centers, but is not risk free, comfortable for the patient, or more sensitive than luminal intubation methods.\(^{165}\)

Indirect tests of pancreatic exocrine function are based on the measurement of metabolites of compounds that are altered
Although the sensitivity of the test is as high as 100% in patients with severe chronic pancreatitis, it identifies only 40% to 50% of patients with mild disease, and reduced PABA excretion is found in patients with a variety of other GI, hepatic, and renal diseases. The quantification of stool fat has also been used as a measure of pancreatic lipase secretion, either through the direct measurement of total fecal fat levels while the subject consumes a diet of known fat content, or by the measurement of exhaled $^{14}$CO$_2$ after ingestion of $[^{14}$C]-triolaen or $[^{14}$C]-olein. This so-called triolein breath test is less cumbersome than intubation methods, and avoids the necessity of stool collections and analysis, but also has a high false-negative rate. Fecal levels of chymotrypsin and elastase have been proposed as simpler, less expensive tests of exocrine function and correlate well with loss of pancreatic function. As with other test methods, however, these tests lose their sensitivity in patients with mild to moderate chronic pancreatitis and may be more sensitive for other causes of pancreatic dysfunction, including cystic fibrosis. Fecal elastase C1 measurements have become widespread in their use, and levels above 200 μg/g are considered normal, whereas levels below 100 μg/g are indicative of pancreatic exocrine insufficiency. The sensitivity and specificity of fecal elastase C1 measurements fall short of those needed for definitive diagnosis of pancreatic exocrine insufficiency, however.

Radiologic imaging has become the principal method of diagnosis of chronic pancreatitis, with the codification of classification systems that correlate with proven disease. ERCP has been considered the most sensitive radiologic test for the diagnosis of chronic pancreatitis, with specific ERCP findings that are highly correlative with the degree or stage of chronic disease (Table 33-15). CT scanning is sensitive for the diagnosis of chronic pancreatitis when calcification, duct dilatation, or cystic disease is present, but is not accurate in the absence of these findings. CT is helpful as a screening study to guide interventional therapy or other diagnostic modalities, although EUS has become the preferred method for the diagnosis of pancreatic disease and offers the advantage of very-high-resolution images of the pancreatic parenchyma, the main and secondary ductal systems, cystic lesions, and calcific changes. EUS findings may be inconclusive in mild or “minimal change” pancreatitis, however, and improved criteria for an EUS-based diagnosis are still a work in progress. Most importantly, EUS is highly reliable in ruling out pancreatic carcinoma when CT findings are normal or equivocal.

### Prognosis and Natural History

The prognosis for patients with chronic pancreatitis is dependent on the etiology of the disease, the development of complications, and on the age and socioeconomic status of the patient. The influence of treatment is less evident in long-term studies, although the general absence of randomized, prospective trials clouds the issue of whether specific forms of therapy alter the long-term outlook for patients with the disease.

Several studies have demonstrated that, although symptoms of pain decrease over time in about half of the patients, this decline is also accompanied by a progression of exocrine and endocrine insufficiency. In general, the likelihood of eventual pain relief is dependent upon the stage of disease at diagnosis, and the persistence of alcohol use in patients with alcoholic chronic pancreatitis. Miyake and colleagues found that pain relief was achieved in 60% of alcoholic patients who successfully discontinued drinking, but in only 26% who did not.

The long-term survival of patients with chronic pancreatitis is less than for patients without pancreatitis. In an international multicenter study of 2000 patients, Lowenfels and colleagues found that the 10- and 20-year survival rates for patients with chronic pancreatitis were 70% and 45%, respectively, compared to 93% and 65% for patients without pancreatitis. The mortality risk was found to be 1.6-fold higher in patients who continued to abuse alcohol, compared to those who did not. Continued alcohol abuse has a similar effect on the response to surgical treatment (Fig. 33-35), and results in a twofold increase in mortality over a 10- to 14-year follow-up period.

In addition to progressive endocrine and exocrine dysfunction, and the risk of the specific complications outlined below and in Table 33-16, the other significant long-term risk for the patient with chronic pancreatitis is the development of pancreatic carcinoma. There is a progressive, cumulative increased risk of carcinoma development in patients with chronic pancreatitis, which continues throughout the subsequent lifetime of the patient (Fig. 33-36). The incidence of carcinoma in patients with chronic pancreatitis ranges from 1.5% to 6%, which is at least 10-fold greater than that of patients of similar age seen in a hospital setting. In a recent study, the risk of carcinoma among patients with chronic pancreatitis accompanied by diabetes was found to be increased 33-fold compared to healthy, comparably aged controls. In patients with advanced chronic pancreatitis referred for surgical therapy, indolent, undiagnosed carcinoma can be seen in as many as 10% of patients.

The development of carcinoma in the setting of chronic pancreatitis is no doubt related to the dysregulation of cellular proliferation and tissue repair processes in the setting of chronic inflammation, as is seen throughout the alimentary tract and elsewhere. In the setting of chronic pancreatitis, carcinoma development can be especially cryptic, and the diagnosis of early-stage tumors is particularly difficult. Awareness of this risk justifies close surveillance for cancer in patients with chronic pancreatitis. Periodic measurement of tumor markers such as CA19-9, and periodic imaging of the pancreas with CT scan and EUS seem logical in order to detect the development of carcinoma in the patient with chronic pancreatitis, although no evidence exists to indicate that this alters the outcome of patients who develop pancreatic cancer. Surgical procedures performed for presumed chronic pancreatitis should always include biopsy of the tissue to exclude the diagnosis of malignancy.

of patients with chronic pancreatitis, and thus, they comprise the most common complication of chronic pancreatitis. The identification and treatment of pseudocysts requires definition of the various forms of pancreatic fluid collections that occur (Table 33-17). In chronic pancreatitis, a pancreatic duct leak with extravasation of pancreatic juice results in a peri-pancreatic fluid collection (PPFC). Over a period of 3 to 4 weeks, the PPFC is sealed by an inflammatory reaction that leads to development of a wall of acute granulation tissue without much fibrosis. This is referred to as an acute pseudocyst. Acute pseudocysts may resolve spontaneously in up to 50% of cases, over a course of 6 weeks or longer. Pseudocysts >6 cm resolve less frequently than smaller ones but may regress over a period of weeks to months. Pseudocysts are multiple in 17% of patients, or may be multilobulated. They may occur intrapancreatically or extend beyond the region of the pancreas into other cavities or compartments (Fig. 33-37).

Pseudocysts may become secondarily infected, in which case they become abscesses. They can compress or obstruct adjacent organs or structures, leading to superior mesenteric-portal vein thrombosis or splenic vein thrombosis. They can erode into visceral arteries and cause intracystic hemorrhage or pseudoaneurysms (Fig. 33-38). They also can perforate and cause peritonitis or intraperitoneal bleeding.

Figure 33-37. Extensive pseudocyst disease. A computed tomographic scan in a patient with alcoholic chronic pancreatitis demonstrates multiloculated pseudocyst disease.

Pseudocysts usually cause symptoms of pain, fullness, or early satiety. Asymptomatic pseudocysts can be managed expectantly and may resolve spontaneously or persist without complication. Symptomatic or enlarging pseudocysts require treatment, and any presumed pseudocyst without a documented antecedent episode of acute pancreatitis requires investigation to determine the etiology of the lesion. Although pseudocysts comprise roughly two thirds of all pancreatic cystic lesions, they resemble cystadenomas and cystadenocarcinoma radiographically. An incidentally discovered cystic lesion should be examined by EUS and aspirated to determine whether it is a true neoplasm or a pseudocyst.

The timing and method of treatment requires careful consideration. Pitfalls in the management of pseudocysts result from the incorrect (presumptive) diagnosis of a cystic neoplasm masquerading as a pseudocyst, a failure to appreciate the solid or debris-filled contents of a pseudocyst that appears to be fluid filled on CT scan, and a failure to document true adherence with

Figure 33-38. Pseudoaneurysm of the gastroduodenal artery. A pseudocyst can erode into an adjacent artery, which results in contained hemorrhage otherwise known as a pseudoaneurysm. A contrast-injected computed tomographic scan reveals active bleeding (area marked B) into a pseudocyst (arrows) as a result of this process. (Reproduced with permission from Balthazar EJ: CT diagnosis and staging of acute pancreatitis. Radiol Clin North Am. 1989;27:19. Copyright Elsevier.)
If infection is suspected, the pseudocyst should be aspirated (not drained) by CT- or US-guided FNA, and the contents examined for organisms by Gram’s stain and culture. If infection is present, and the contents resemble pus, external drainage is employed, using either surgical or percutaneous techniques.

If the pseudocyst has failed to resolve with conservative therapy, and symptoms persist, internal drainage is usually preferred to external drainage, to avoid the complication of a pancreaticocutaneous fistula. Pseudocysts communicate with the pancreatic ductal system in up to 80% of cases, so external drainage creates a pathway for pancreatic duct leakage to and through the catheter exit site. Internal drainage may be performed with either percutaneous catheter-based methods (transgastric puncture and stent placement to create a cystogastrostomy), endoscopic methods (transgastric or transduodenal puncture and multiple stent placements, with or without a nasocystic irrigation catheter), or surgical methods (a true cystoenterostomy, biopsy of cyst wall, and evacuation of all debris and contents). Surgical options include a cystogastrostomy (Fig. 33-39), a Roux-en-Y cystojejunostomy, or a cystoduodenostomy. Cystojejunostomy is the most versatile method, and it can be applied to pseudocysts that penetrate into the transverse mesocolon, the paracolic gutters, or the lesser sac. Cystogastrostomy can be performed endoscopically or by a combined laparoscopic-endoscopic method.

Because pseudocysts often communicate with the pancreatic ductal system, two newer approaches to pseudocyst management are based on main duct drainage, rather than pseudocyst drainage per se. Transpapillary stents inserted at the time of ERCP may be directed into a pseudocyst through the ductal communication itself (Fig. 33-41), or can be left across the area of suspected duct leakage to facilitate decompression and cyst drainage, analogous to the use of common bile duct stents in the setting of a cystic duct leak. In a surgical series of patients with chronic pancreatitis, ductal dilation, and a coexisting pseudocyst, Nealon and Walser showed that duct drainage alone, without a separate cystoenteric anastomosis, was as successful as a combined drainage procedure. Furthermore, the “duct drainage only” group enjoyed a shorter hospital stay and fewer complications than the group who underwent a separate cystoenterostomy. These observations suggest that transduodenal drainage may be a safe and effective approach to the management of pseudocystic disease.

The complications of endoscopic or radiologic drainage of pseudocysts often require surgical intervention. Bleeding from the cystoenterostomy, and inoculation of a pseudocyst with failure of resolution and persistence of infection, may require surgical treatment. Bleeding risks may be lessened by the routine use of EUS in the selection of the site for transluminal stent placement. Percutaneous and endoscopic treatment of pseudocysts requires large-bore catheters, multiple stents, and an aggressive approach to management for success to be achieved. Failure of nonsurgical therapy, with subsequent salvage procedures to remove infected debris and establish complete drainage, is associated with increased risks for complications and death. The most experienced therapeutic endoscopists report a complication rate of 17% to 19% for the treatment of sterile cystoenterostomy.
pseudocysts, and deaths as a result of endoscopic therapy have occurred. Therefore, the use of endoscopic methods to treat sterile or infected pancreatic necrosis has a higher complication rate and is limited to specialized centers.

Resection of a pseudocyst is sometimes indicated for cysts located in the pancreatic tail, or when a midpancreatic duct disruption has resulted in a distally located pseudocyst. Distal pancreatectomy for removal of a pseudocyst, with or without splenectomy, can be a challenging procedure in the setting of prior pancreatitis. An internal drainage procedure of the communicating duct or of the pseudocyst itself should be considered when distal resection is being contemplated.

Pancreatic Ascites. When a disrupted pancreatic duct leads to pancreatic fluid extravasation that does not become sequestered as a pseudocyst, but drains freely into the peritoneal cavity, pancreatic ascites occurs. Occasionally, the pancreatic fluid tracks superiorly into the thorax, and a pancreatic pleural effusion occurs. Referred to as internal pancreatic fistulae, both complications are seen more often in patients with chronic pancreatitis rather than after acute pancreatitis. Pancreatic ascites and pleural effusion occur together in 14% of patients, and 18% have a pancreatic pleural effusion alone.

Patients demonstrate the general demographics of chronic pancreatitis and usually present with a subacute or recent history of progressive abdominal swelling despite weight loss. Pain and nausea are rarely present. The abdominal CT scan discloses ascites and the presence of chronic pancreatitis or a partially collapsed pseudocyst (Fig. 33-42). Paracentesis or thoracentesis reveals noninfected fluid with a protein level >25 g/L and a markedly elevated amylase level. Serum amylase may also be elevated, presumably from reabsorption across the parietal membrane. Serum albumin may be low, and patients may have coexisting liver disease. Paracentesis is therefore critical to differentiate pancreatic from hepatic ascites.

ERCP is most helpful to delineate the location of the pancreatic duct leak and to elucidate the underlying pancreatic ductal anatomy. Pancreatic duct stenting may be considered at the time of ERCP, but if nonsurgical therapy is undertaken and then abandoned, repeat imaging of the pancreatic duct is appropriate to guide surgical treatment.

Antisecretory therapy with the somatostatin analogue octreotide acetate, together with bowel rest and parenteral nutrition, is successful in more than half of patients. Reapposition of serosal surfaces to facilitate closure of the leak is considered a part of therapy, and this is accomplished by complete paracentesis. For pleural effusions, a period of chest tube drainage may facilitate closure of the internal fistula. Surgical therapy is reserved for those who fail to respond to medical treatment. If the leak originates from the central region of the pancreas, a Roux-en-Y pancreaticojejunostomy is performed to the site of duct leakage (Fig. 33-43). If the leak is in the tail, a distal pancreatectomy may be considered, or an internal drainage procedure can be performed. The results of surgical treatment are usually favorable if the ductal anatomy has been carefully delineated preoperatively.

Pancreatic-Enteric Fistula. The erosion of a pancreatic pseudocyst into an adjacent hollow viscus can result in a pancreatic-enteric fistula. The most common site of communication is the transverse colon or splenic flexure. The fistula usually presents with evidence of GI or colonic bleeding and sepsis. If the fistula communicates with the stomach or duodenum, it may close spontaneously or persist as a pancreatic-enteric fistula. When the fistula involves the colon, operative correction is usually required.
they are difficult to treat successfully. Portal vein compression and occlusion can occur as a consequence of an inflammatory mass in the head of the pancreas, and splenic vein thrombosis occurs in association with chronic pancreatitis in 4% to 8% of cases. Variceal formation can occur as a consequence of either portal or splenic venous occlusion, and splenic vein thrombosis with gastric variceal formation is referred to as left-sided or sinistral portal hypertension. Although bleeding complications are infrequent, the mortality risk of bleeding is >20%. When gastroesophageal varices are caused by splenic vein thrombosis, the addition of splenectomy to prevent variceal hemorrhage is prudent when surgery is otherwise indicated to correct other problems.

**Treatment**

**Medical Therapy.** The medical treatment of chronic or recurrent pain in chronic pancreatitis requires the use of analgesics, a cessation of alcohol use, oral enzyme therapy, and the selective use of antisecretory therapy. Interventional procedures to block visceral afferent nerve conduction or to treat obstructions of the main pancreatic duct are also an adjunct to medical treatment.

**Analgesia.** Oral analgesics are prescribed as needed, alone or with analgesia-enhancing agents such as gabapentin. Adequate pain control usually requires the use of narcotics, but these should be titrated to achieve pain relief with the lowest effective dose. Opioid addiction is common, and the use of long-acting analgesics by transdermal patch together with oral agents for pain exacerbations slightly reduces the sedative effects of high-dose oral narcotics.

It is essential for patients to abstain from alcohol. In addition to removing the causative agent, alcohol abstinence results in pain reduction or relief in 60% to 75% of patients with chronic pancreatitis. Despite this benefit, roughly half of alcoholic chronic pancreatitis patients continue to abuse alcohol.

**Enzyme Therapy.** Pancreatic enzyme administration serves to reverse the effects of pancreatic exocrine insufficiency. Adequate pancreatic enzyme replacement reverses the exocrine insufficiency seen in most patients, and prevents secondary complications such as metabolic bone disease due to inadequate absorption of the fat-soluble vitamins A, D, E, and K. In addition, pancreatic enzyme replacement may reduce or alleviate the pain experienced by patients. The choice of enzyme supplement and the dose should be selected based on whether malabsorption or pain (or both) are the indications for therapy. Conventional (nonenteric-coated) enzyme preparations are partially degraded by gastric acid but are available within the duodenal and jejunal regions to bind to CCK-releasing peptide, and downregulate the release of CCK. This theoretically reduces the enteric signal for pancreatic exocrine secretion, which reduces the pressure within a partially or completely obstructed pancreatic duct. Enteric-coated preparations result in little to no pain relief, presumably due to their reduced bioavailability in the proximal gut. Due to the loss of pancreatic enzymes by acid hydrolysis and proteolysis, relatively large doses are required to achieve effective levels of enzyme within the proximal small bowel. Enteric-coated preparations are protected from acid degradation but are presumably not released in the critical proximal gut in sufficient quantity to inhibit the stimulus for endogenous pancreatic enzyme secretion. Nonalcoholic patients may experience more effective pain relief than alcoholic patients, but it is recommended that all patients with chronic pancreatitis pain

---

**Head-of-Pancreas Mass.** In up to 30% of patients with advanced chronic pancreatitis, an inflammatory mass develops in the head of the pancreas. The clinical presentation includes severe pain, and frequently includes stenosis of the distal common bile duct, duodenal stenosis, compression of the portal vein, and stenosis of the proximal main pancreatic duct (Table 33-18). Mutations and polymorphisms of p53 have been found in these patients, and a focus of ductular carcinoma was found in 3.7% of patients with pancreatic head enlargement, although the etiology for this process remains unclear.

**Splenic and Portal Vein Thrombosis.** Vascular complications of chronic pancreatitis are fortunately infrequent, because

USP: United States Pharmacopeia, the standard for lipase content in the United States. An average meal requires roughly 90,000 USP units of lipase for fat digestion. Enzyme therapy of exocrine deficiency typically begins with a dose of 50,000 USP units per meal with subsequent adjustment.

begin a trial of nonenteric-coated enzyme supplements together with an acid-suppressive medication for 1 month. If pain relief is achieved, therapy is continued. If enzyme therapy fails, further investigation of the pancreatic ductal system by ERCP guides the therapy based on specific anatomical findings (Fig. 33-44).

**Antisecretory Therapy.** Somatostatin administration has been shown to inhibit pancreatic exocrine secretion and CCK release.203 The somatostatin analogue octreotide has therefore been investigated for pain relief in patients with chronic pancreatitis. In a double-blind, prospective, randomized 4-week trial, 65% of patients who received 200 μg of octreotide acetate subcutaneously three times daily reported pain relief, compared with 35% of placebo-treated subjects.204 Patients who had the best results were patients with chronic abdominal pain, suggestive of obstructive pancreatopathy. However, in another trial that used a 3-day duration of treatment, no significant pain relief was observed.205 Anecdotal reports suggest that severe pain exacerbations in chronic pancreatitis can benefit from a combination of octreotide therapy and TPN, and a pilot study of the effectiveness of the sustained-release form of octreotide suggested that it was as effective as three-times-per-day administration of the short-acting form of the drug.206

**Neurolytic Therapy.** Celiac plexus neurolysis with alcohol injection has been an effective form of analgesic treatment in patients with pancreatic carcinoma. However, the use of radiologically- or endoscopically-guided celiac plexus blockade in chronic pancreatitis has been disappointing. Due to the risk of alcohol injury and the need for repeated injections, celiac plexus blockade in chronic pancreatitis has used short-acting analgesics or other drugs rather than 50% alcohol. A trial of EUS-guided celiac plexus blockade revealed successful pain relief in 55% of patients, but the benefit lasted beyond 6 months in only 10% of patients.207 The procedure therefore appears safe, but the effect is short lived in those patients who obtain pain relief.

**Endoscopic Management.** The techniques of endoscopic treatment of pancreatic duct obstruction, stone disease, pseudocyst formation, pancreatic duct leak, and for the diagnosis and management of associated pancreatic tumors have expanded greatly over the past 10 years. Newer endoscopes with expanded therapeutic capabilities have been introduced, and the role of EUS and EUS-guided needle and catheter insertion has expanded the ability of the therapeutic endoscopist in the diagnosis and treatment of chronic pancreatitis and its complications.208

Pancreatic duct stenting is used for treatment of proximal pancreatic duct stenosis, decompression of a pancreatic duct leak, and for drainage of pancreatic pseudocysts that can be catheterized through the main pancreatic duct. Pancreatic duct stents can induce an inflammatory response within the duct, so prolonged stenting is usually avoided. Patients with sphincter of Oddi dyskinesia are at high risk for developing post-ERCP pancreatitis after biliary sphincterotomy, and the prophylactic placement of a pancreatic duct stent reduces the amylase level and development of pancreatitis after biliary sphincterotomy.209 Pancreatic duct leaks are seen in 37% of patients with acute pancreatitis, and pancreatic duct stenting appear to facilitate the resolution of the leak.210 Similarly, pancreatic duct stenting has been used to treat postsurgical pancreatic duct leaks and post-traumatic leaks.210–212

Pancreas divisum (see Fig. 33-3) is thought to cause pain and chronic pancreatitis due to functional or mechanical obstruction of the dorsal duct draining exclusively, or predominantly, through the lesser papilla. A study from Marseille reported good long-term results in 24 patients after minor papilla sphincterotomy and dorsal duct stenting.213 The number of patients with chronic pain decreased from 83% before stenting to 29% after stenting, but pancreatitis or recurrent papillary stenosis occurred in 38%. Patients that responded best were those with intermittent pain, and this subset may be preferentially treated with endoscopic therapy.

Idiopathic pancreatitis patients have been treated with endoscopic stenting, pancreatic duct sphincterotomy, and endoscopic stone removal with good results. In a prospective randomized trial, 53% of idiopathic recurrent pancreatitis patients in the control group experienced continued episodes of pancreatitis, although only 11% of the treated patients had continued symptoms.214

Extracorporeal shock wave lithotripsy (ESWL) has been used for pancreatic duct stones, together with endoscopic stenting and stone removal.215 A single ESWL session was used in 35 patients with pancreatic duct stones, together with 86 ERCP sessions to complete the stone removal process. After 2.4 years,

He later the option B Mild to moderate 8 (22%); severe Obtaining good surgical outcomes before the report in 24-M No other therapy (or lack thereof) that further medical and endoscopic therapy will halt the symptoms of the disease, and the chance that a good result will be obtained with the lowest risk of morbidity and mortality. Finally, preparation for surgery should include restoration of protein-caloric homeostasis, abstinence from alcohol and tobacco, and a detailed review of the risks and likely outcomes to establish a bond of trust and commitment between the patient and the surgeon.

Historically, the surgery for chronic pancreatitis before the second half of the twentieth century was a true demonstration of trial and error. Obtaining good surgical outcomes before the availability of CT scans and ERCP was either the result of serendipity or due to the skill and creativity of the surgeon. In 1911, Link described an operation he devised on the spot, when a laparotomy in a young woman with abdominal pain revealed a fluctuant, obstructed pancreatic duct. After performing a dochotomy and evacuating multiple stones, he inserted a rubber tube, and exteriorized the pancreateostomy just above her navel. He later described the operation as having been a success for the next 30 years of the patient’s life, during which the patient managed the care of the drainage tube without apparent problems.

With the demonstration in 1942 by Priestley that total pancreatectomy was technically feasible, and the report in 1946 by Whipple that proximal pancreatic resection was beneficial in (three) patients with chronic pancreatitis, the option of surgical resection as treatment for chronic pancreatitis was established. By the mid 1950s, however, growing disappointment with the high risk of resection and the lack of long-term benefit overshadowed the surgical treatment of chronic pancreatitis. The choice of resection vs. drainage was largely based on surgeon preference until the 1970s, when the widespread adoption of ERCP and CT scans provided the ability to preoperatively diagnose obstructive and sclerotic disease, and this resulted in the rational selection of operative procedures. During this period, the major drawbacks to surgical therapy remained the recurrence of symptoms despite surgery, the corresponding development of an inflammatory (or malignant) mass in the undrained pancreatic head (Fig. 33-46), or the high morbidity and mortality of major resectional procedures that seemed to predispose the patients to a cascade of metabolic problems.

Eighty-three patients with chronic pancreatitis were evaluated by exocrine, endocrine, nutritional, and endoscopic retrograde cholangiopancreatography studies, and all had mild to moderate disease and dilated pancreatic ducts. A Puestow-type duct decompression procedure was performed in 47 patients, and all subjects were restaged by the same methods 24 months later. Source: Reproduced with permission from Nealon et al.216

Historically, the surgery for chronic pancreatitis before the second half of the twentieth century was a true demonstration of trial and error.17 Obtaining good surgical outcomes before the availability of CT scans and ERCP was either the result of serendipity or due to the skill and creativity of the surgeon. In 1911, Link described an operation he devised on the spot, when a laparotomy in a young woman with abdominal pain revealed a fluctuant, obstructed pancreatic duct. After performing a dochotomy and evacuating multiple stones, he inserted a rubber tube, and exteriorized the pancreateostomy just above her navel. He later described the operation as having been a success for the next 30 years of the patient’s life, during which the patient managed the care of the drainage tube without apparent problems.216

Sphincteroplasty The sphincter of Oddi and the pancreatic duct sphincter serve as gatekeepers for the passage of pancreatic juice into the duodenum (Fig. 33-47). Stenosis of either sphinc
(sclerosing papillitis), due to scarring from pancreatitis or from the passage of gallstones, may result in obstruction of the pancreatic duct and chronic pain. As gallstone pancreatitis became a popular diagnosis in the 1940s and 1950s, attention was focused on the ampullary region as a possible cause of chronic symptoms, and surgical sphincteroplasty was advocated. Although endoscopic techniques are now used routinely to perform sphincterotomy of either the common bile duct or pancreatic duct, a true (permanent) sphincteroplasty can only be performed surgically. Transduodenal sphincteroplasty with incision of the septum between the pancreatic duct and common bile duct appears to offer significant relief for patients with obstruction and inflammation isolated to this region (Fig. 33-48).

Drainage Procedures. After the early reports of success with pancreatostomy for the relief of symptoms of chronic pancreatitis, Cattell described pancreaticojejunostomy for relief of pain in unresectable pancreatic carcinoma. Shortly thereafter, Duval, and separately, Zollinger and associates, described the caudal Roux-en-Y pancreaticojejunostomy for the treatment of chronic pancreatitis in 1954 (Fig. 33-49). The so-called Duval procedure was used for decades by some surgeons, but it almost invariably failed due to restenosis and segmental obstruction of the pancreas due to progressive scarring. In 1958, Puestow and Gillesby described these segmental narrowings and dilatations of the ductal system as a “chain of lakes,” and proposed a longitudinal decompression of the body and tail of the pancreas into a Roux limb of jejunum (Fig. 33-50). Four of Puestow and Gillesby’s 21 initial cases were side-to-side anastomoses, and 2 years after their report, Partington and Rochelle described a much simpler version of the longitudinal, or side-to-side Roux-en-Y pancreaticojejunostomy that became universally known as the Puestow procedure (Fig. 33-51).

The effectiveness of decompression of the pancreatic duct is dependent on the extent to which ductal hypertension is the etiologic agent for the disease. Thus, the diameter of the pancreatic duct is a surrogate for the degree of ductal hypertension, and the Puestow procedure has been shown to be effective for pain relief when the maximum duct diameter is 6 mm. Results are less impressive in glands with smaller caliber ducts, although Izbicki and associates have described good results with a conization method that allows a longitudinal decompression of more normal caliber ducts. Successful pain relief after the Puestow-type decompression procedure has been reported in 75% to 85% of patients for the first few years after surgery, but pain recurs in >20% of patients after 5 years, even in patients who are abstinent from alcohol.

With the advent of therapeutic endoscopy and techniques for transluminal stone removal and lithotripsy, multiple series have reported the successful endoscopic treatment of pancreatic duct calculi, although the long-term outcomes of these efforts has been uneven. Endoscopic removal of pancreatic duct stones is usually coupled to prolonged pancreatic duct stenting, which carries the risk of further inflammation. Despite the risk of perioperative
complications, the surgical management of pancreatic duct stones and stenosis has been shown to be superior to endoscopic treatment in randomized clinical trials in which the long, side-to-side technique of pancreaticojejunostomy is used.236,237

Figure 33-48. Operative sphincteroplasty of the biliary and pancreatic duct. The ampullary and bile duct sphincters are divided, as is the pancreatic duct sphincter, with suture apposition of the mucosal edges of the incision. (Data from Moody et al.223)

Resectional Procedures

Distal Pancreatectomy For patients with focal inflammatory changes localized to the body and tail, or in whom no significant ductal dilatation exists, the technique of partial (40%–80%) distal pancreatectomy has been advocated (Fig. 33-52). Although distal pancreatectomy is less morbid than more extensive resectional procedures, the operation leaves untreated a major portion of the gland, and is therefore associated with a significant risk of symptomatic recurrence. It has been a more popular operation in British centers, where its success seems to be greater, perhaps due to the lower incidence of alcoholic chronic pancreatitis.238 However, long-term outcomes reveal good pain relief in only 60% of patients, with completion pancreatectomy required for pain relief in 13% of patients.

Laparoscopic distal pancreatectomy has been shown to be feasible for the removal of focal lesions of the distal pancreas239 but is more difficult in the setting of chronic pancreatitis.

Ninety-Five Percent Distal Pancreatectomy In 1965, Fry and Child proposed the more radical 95% distal pancreatectomy, which was intended for patients with sclerotic (small duct) disease, and which attempted to avoid the morbidity of total pancreatectomy by preserving the rim of pancreas in the pancreaticoduodenal groove, along with its associated blood vessels and distal common bile duct.222 The operation was found to be associated with pain relief in 60% to 77% of patients long term, but is accompanied by a high risk of brittle diabetes, hypoglycemic coma, and malnutrition.240 Although the operation was the first attempt to resect the pancreatic head while preserving the duodenum and distal bile duct, the extensive degree of pancreatic removal led to its failure as viable treatment for the symptoms of pancreatic sclerosis.
Proximal Pancreatectomy In 1946, Whipple reported a series of five patients treated with either pancreaticoduodenectomy or total pancreatectomy for symptomatic chronic pancreatitis, with one operative death. Subsequently, proximal pancreatectomy or pancreaticoduodenectomy, with or without pylorus preservation (Fig. 33-53), has been widely used for the treatment of chronic pancreatitis. In the three largest modern (circa 2000) series of the treatment of chronic pancreatitis by the Whipple procedure, pain relief 4 to 6 years after operation was found in 71% to 89% of patients. However, mortality ranged from 1.5% to 3%, and major complications occurred in 25% to 38% of patients at the Johns Hopkins Hospital, the Mayo Clinic, and the Massachusetts General Hospital. In follow-up, 25% to 48% of patients developed diabetes, and about the same percentage required exocrine therapy. Advocates of the Whipple procedure uniformly suggest that the high rate of symptomatic relief outweighs the metabolic consequences and the mortality risk of the procedure.

Total Pancreatectomy Priestley and associates first described successful total pancreatectomy in 1944 in a patient with hyperinsulinism, and two of Whipple’s original five cases of chronic pancreatitis reported in 1946 were treated with total pancreatectomy. Subsequently, surgeons who used total pancreatectomy found that the operation produces no better pain relief for their patients than pancreaticoduodenectomy (about 80%–85%). Moreover, the metabolic consequences of total pancreatectomy in the absence of islet cell transplantation are profound and life-threatening. The patients have a “brittle” form of diabetes in which avoidance of hyper- and hypoglycemia is problematic. In addition, lethal episodes of hypoglycemia are common in severe apancreatic diabetes. These are due to hypoglycemic unresponsiveness, due to the absence of pancreatic glucagon, and to hypoglycemia unawareness, despite an ongoing need to treat with exogenous insulin. In a series of >100 patients treated with total pancreatectomy, Gall and colleagues showed that half of all the late deaths after this operation were due to (iatrogenic) hypoglycemia. Despite newer forms of insulin, insulin delivery systems, and blood glucose monitoring, severe pancreateogenic diabetes remains an adverse outcome, as complete prevention of the physiologic consequences of total pancreatectomy remains an unfulfilled goal. With the growing acceptance of islet auto-transplantation as an adjunct to the procedure (see below), total pancreatectomy itself is now used only rarely for the treatment of refractory chronic pancreatitis.

Hybrid Procedures In 1980, Beger and associates described the Duodenum-preserving Pancreatic Head Resection or DPPHR procedure.
In 388 patients who were followed for an average of 6 years after DPPHR, pain relief was reportedly maintained in 91%, mortality was <1%, and diabetes developed in 21%, with 11% demonstrating a reversal of their preoperative diabetic status. These authors also compared the DPPHR procedure with the pylorus-sparing Whipple procedure in a randomized trial of 40 patients with chronic pancreatitis. The mortality was reportedly zero in both groups, and the morbidity was also comparable. Pain relief (over 6 months) was seen in 94% of DPPHR patients, but in only 67% of Whipple patients. Furthermore, the insulin secretory capacity and glucose tolerance were noted to deteriorate in the Whipple group, but actually improved in the DPPHR patients.

The DPPHR requires the careful dissection of the gastroduodenal artery and the creation of two anastomoses (Fig. 33-55), and carries a similar complication risk as the Whipple procedure due to the risk of pancreatic leakage and intra-abdominal fluid collections.

In 1987, Frey and Smith described the local resection of the pancreatic head with longitudinal pancreaticojejunostomy (LR-LPJ), which included excavation of the pancreatic head, including the ductal structures in continuity with a long dichotomy of the dorsal duct (Fig. 33-56). The Frey procedure provides thorough decompression of the pancreatic head as well as the body and tail of the gland, and a long-term follow-up suggested that improved outcomes are associated with this more extensive decompressive procedure. Frey and Amikura reported their results in 50 patients followed for >7 years, and found complete or substantial pain relief in 87% of patients. There was no operative mortality, but 22% of patients developed postoperative complications.

Key steps in the performance of the LR-LPJ include preservation of the pancreatic neck as well as the capsule of the posterior pancreatic head. In the pancreaticoduodenectomy and the DPPHR, the pancreatic neck is freed up from the portal and superior mesenteric vein confluence and divided. In the LR-LPJ, the neck of the pancreas is preserved intact as are the body and tail of the pancreas. Not having to divide the pancreatic neck, as in the pancreaticoduodenectomy or DPPHR, reduces the risk of the operation, as it avoids intraoperative problems with the venous structures lying posterior to the gland. To reduce the risk of penetrating the posterior capsule of the head, Frey recommended in his 1994 report that the posterior limit of resection be the back wall of the opened duct of Wirsung and duct to the uncinate (Fig. 33-57).

Subsequent to Frey’s own modification of the technique, other surgeons have described modifications of the extent or technique of the LR-LPJ. Andersen and Topazian advocated performing the LR-LPJ as it was originally described, in which the entirety of the ducts are excised from the head (Fig. 33-58), and described the use of the ultrasonic aspirator and dissector for this purpose. The use of this device permits precise removal of the ducts and adjacent tissue with good visualization and without complications. There is little pancreatic tissue behind these ducts and the pancreatic capsule is continuously palpated as the dissection proceeds to ensure a safe margin of resection. The intrapancreatic portion of the common bile duct is usually exposed, and avoiding injury to it is enhanced by the ultrasonic aspirator. The majority of the parenchyma of the uncinate process is spared, and the excavation of the pancreatic head is made contiguous with a generous dochotomy of the dorsal duct. Whether merely unroofing as opposed to removal of the proximal ducts contributes to better pain relief is not known and awaits a randomized trial to compare the two versions of the LR-LPJ. Izbicki and colleagues at the University of Hamburg also recommend a more extensive excision of the pancreatic head, and use a technique that they refer to as the Hamburg modification of the LR-LPJ (Fig. 33-59). This wider excavation of the pancreatic head is created in continuity with the dorsal dochotomy, and is followed by a single, side-to-side pancreaticojejunostomy.
In 2001, Ho and Frey subsequently described merely excavating the core of the pancreatic head, and draining the excava-
tion with a Roux-en-Y pancreaticojejunostomy, but without
any effort to include the dorsal duct. In 2003, Farkas and
colleagues described a similar excavation of the cen-
tral portion of the pancreatic head without any effort to include
the duct of the body in the lateral pancreaticojejunostomy,
and reported excellent results with what they termed an
organ-preserving pancreatic head resection (OPPHR) in a randomized
trial of the "Berne" version of the excavation method compared
to the "classic" Beger procedure. Operative times and length
of stay were shorter in the group undergoing excavation of the
pancreatic head, while long-term outcomes and quality-of-life
scores were identical over 2 years postoperatively.

The common element of these variations on the theme of
LR-LPJ remains the excavation or "coring out" of the central
portion of the head of the gland. It remains uncertain, however,
whether and to what degree the dochotomy needs to be extended
into the body and tail. The logical conclusion of all of
these efforts is that the head of the pancreas is the nidus
of the chronic inflammatory process in chronic pancreatitis, and
that removal of the central portion of the head of the gland is the
key to the successful resolution of pain long-term.

Complications Initial and long-term results of the LR-LPJ
demonstrate pain relief that is equivalent to that of pancreati-
coduodenectomy and the DPPHR. The observed mortality
rate has been virtually zero, and therefore, less than with
the Whipple procedure. Major complications were less with the
LR-LPJ (16%) than with pancreaticoduodenectomy (40%) or
DPPHR (25%) in one single-site series, and the incidence of
new postoperative diabetes after LR-LPJ was 8% with an aver-
age follow-up of 3 years.

Comparisons of the three operative procedures: Pancreaticodu-
dodenectomy (Whipple procedure), DPPHR (Beger procedure),
and LR-LPJ (Frey procedure). There has been considerable
interest to apply evidence-based methods to the study of the
three operations currently advocated for the treatment of
Figure 33-56. Frey procedure. The local resection of the pancreatic head with longitudinal pancreaticojejunostomy (LR-LPJ) provides complete decompression of the entire pancreatic ductal system. Reconstruction is performed with a side-to-side Roux-en-Y pancreaticojejunostomy. (Reproduced with permission from Bell.188)

Figure 33-57. Operative view of excavated head of the pancreas during the Frey procedure. The main pancreatic duct is opened widely down to the level of the ampulla, and the head of the pancreas is excavated in a conical fashion so as to allow complete decompression of the chronically obstructed and inflamed pancreatic ducts. chronic pancreatitis. The best studies, or level 1 data by the Strength of Recommendation Taxonomy, are prospective, randomized controlled trials comparing two or more operations from a single or multi-institutional study. Retrospective, cohort-based studies are regarded as level 2 data by the Strength of Recommendation Taxonomy criteria.

To date, six published level 1 studies and three level 2 studies have examined various comparisons between these three operations. In the level 1 study of 43 patients by Klemper and colleagues, DPPHR patients had a shorter hospital stay, greater weight gain, less postoperative diabetes, and exocrine dysfunction than standard Whipple patients over a 3- to 5-year follow-up. Pain control was similar between the two procedures. This was confirmed in a level 1 study of 40 patients by Buchler and associates, in which DPPHR patients reported better pain relief, glucose tolerance, and weight gain compared to pylorus-preserving pancreaticoduodenectomy (PPPD) patients; however, the follow-up averaged <1 year. Similar results were observed in a recent level 2 retrospective study of 123 patients.

In a level 1 study of 61 patients randomized to PPPD or LR-LPJ, Izbicki and colleagues found a lower postoperative complication rate associated with the Frey procedure (19%) compared to the PPPD group (53%), and better global quality-of-life scores (71% vs. 43%, respectively). Both operations were equally effective in controlling pain over a 2-year follow-up. More recently, the level 1 study by Farkas and associates examined 40 patients randomized to PPPD or the method of excavation of the pancreatic head that their group described as an organ-preserving pancreatic head resection (OPPHR), and found that OPPHR was associated with a shorter operating time,
less postoperative morbidity, shorter hospital stay, and better quality of life than PPPD. The degree of pain relief was equal over a 1- to 3-year follow-up. Operation times have been shown to be shorter with the LR-LPJ and DPPHR compared to the PPPD, and intraoperative blood loss and perioperative transfusion requirements are less with LR-LPJ and DPPHR procedures.

Late Morbidity and Mortality

In 2005, Izbicki’s group reported on a level 1 study of 74 patients randomized to the DPPHR or LR-LPJ who were then followed for an average of 8.5 years.208 There were no significant differences between the groups with regard to global quality of life, pain scores, late mortality, and exocrine or endocrine insufficiency. The level 1 study by König, which compared the classic DPPHR with excavation of the pancreatic head, showed identical outcomes at 2 years after an initial reduction in morbidity associated with the excavation procedure.209 These results were echoed in the level 2 study by Aspelund and associates, which demonstrated fewer complications with both the DPPHR and LR-LPJ procedures compared to pancreaticoduodenectomy, a lower incidence of new diabetes (8%) for both DPPHR and LR-LPJ compared to the Whipple procedure (25%), but no significant differences in outcomes or pain relief between DPPHR and LR-LPJ.179 Finally, level 2 data support the efficacy of both DPPHR and LR-LPJ in patients with dilated as well as nondilated ducts.210-212 Long-term exocrine and/or endocrine insufficiency in chronic pancreatitis patients treated surgically is a product of the surgical intervention as well as the progression of the underlying disease. Although the short-term (3-year) incidence of new diabetes after operation appears less with the LR-LPJ and DPPHR than with the PPPD, the late incidence of diabetes appears similar in all groups. After an average of 7 years of follow-up after LR-LPJ or PPPD, survival, pain relief, and pancreatic function were similar in both groups. The rate of diabetes was slightly lower after LR-LPJ (61%) than after PPPD (65%), but these had both more than doubled from their preoperative status.213-216 Therefore, although the limited pancreatic procedures of DPPHR and LR-LPJ have a lower initial rate of endocrine dysfunction, the long-term risk of diabetes is more related to the progression of the underlying disease than to the effects of operation.

The decreased incidence of postoperative diabetes in the near-term after the duodenum-sparing operations may be the result of a preserved β-cell mass in the more conservative resections, and may also be due to the conservation of the PP-secreting cells localized to the posterior head and uncinate process. Preservation of near-normal glucose metabolism and the avoidance of pancreatogenic diabetes is therefore a significant but time-limited benefit of the newer operative procedures.

Total Pancreatectomy with Islet Auto-Transplantation

Islet cell transplantation for the treatment of diabetes is an attractive adjunct to pancreatic surgery in the treatment of benign pancreatic disease, but problems due to rejection of allotransplanted islets have plagued this method since its initial clinical application in the early 1970s. However, despite the difficulties in recovering islets from a chronically inflamed gland, Najarian and associates demonstrated the utility of autotransplantation of islets in patients with chronic pancreatitis in 1980.217 Subsequently, through refinements in the methods of harvesting and gland preservation, and through standardization of the methods by which islets are infused into the portal venous circuit for intrahepatic engraftment, the success of total pancreatectomy combined with islet auto-transplantation has steadily increased to achieve insulin independence in the majority of patients treated in recent series.218-219 Although 2 to 3 million islets are required for successful engraftment in an allogeneic recipient, the auto-transplant recipient can usually achieve long-term, insulin-independent status after engraftment of only 300,000 to 400,000 islets.220

The ability to recover a sufficient quantity of islets from a sclerotic gland is dependent on the degree of fibrotic disease present, so the selection of patients as candidates for autologous islet transplantation is important. The impressive improvement in quality of life measures and pain relief seen after total pancreatectomy with islet auto-transplantation (TP-IAT) indicate that it is a highly successful form of therapy for some patients. The significant morbidity risk of TP-IAT, and the likelihood of unsuccessful recovery of sufficient numbers of islets due to advanced disease, however, suggest that further definition is needed regarding criteria for considering TP-IAT vs. hybrid or resectional procedures for patients with persistent symptoms.

The recent study which compared degree of fibrosis with the extent of pain relief after the LR-LPJ procedure suggests that the extent of pancreatic fibrosis may be a useful guide to the selection of surgical therapy for refractory symptomatic chronic pancreatitis.147 Further studies will require accurate methods to quantify the extent of fibrosis preoperatively.

PANCREATIC NEOPLASMS

Neoplasms of the Endocrine Pancreas

Neoplasms of the endocrine pancreas are relatively uncommon but do occur with enough frequency (five cases per million population) that most surgeons will encounter them in an urban practice. The cells of the endocrine pancreas, or islet cells, originate from neural crest cells, also referred to as amine precursor uptake and decarboxylation cells. Multiple endocrine neoplasia (MEN) syndromes occur when these cells cause tumors in multiple sites. The MEN1 syndrome involves pituitary tumors, parathyroid hyperplasia, and pancreatic neoplasms. Some pancreatic endocrine neoplasms are functional, secreting peptide products that produce interesting clinical presentations. Neoplasms of the endocrine pancreas that are not associated with excess hormone levels and a recognizable clinical syndrome are considered nonfunctional. Special immunohistochemical stains allow pathologists to confirm the peptide products being produced within the cells of a pancreatic endocrine tumor. However, the histologic characteristics of these neoplasms do not predict their clinical behavior, and malignancy is usually determined by the presence of local invasion and lymph node or hepatic metastases. Unfortunately, most pancreatic endocrine tumors are malignant, but the course of the disease is far more favorable than that seen with pancreatic exocrine cancer. The key to diagnosing these rare tumors is recognition of the classic clinical syndrome; confirmation is achieved by measuring serum levels of the elevated hormone. Localization of the tumor can be a challenging step, but once accomplished, the surgery is relatively straightforward. The goals of surgery range from complete resection, often accomplished with insulinomas, to controlling symptoms with debulking procedures. Unresectable disease in the liver is often addressed with chemoembolization.

As with pancreatic exocrine tumors, the initial diagnostic imaging test of choice for pancreatic endocrine tumors is a multidetector CT scan with four phases of contrast and fine cuts through the pancreas and liver. Neuroendocrine tumors of the
pancreas often enhance with contrast. EUS also can be valuable in localizing these tumors, which can produce dramatic symptoms despite their small (<1 cm) size. In contrast to pancreatic exocrine tumors, many of the endocrine tumors have somatostatin receptors (SSTRs) that allow them to be detected by a radiolabeled octreotide scan. A radioactive somatostatin analogue is injected intravenously, followed by whole-body radionuclide scanning (Fig. 33-62). The success of this modality in localizing tumors and detecting metastases has decreased the use of older techniques such as angiography and selective venous sampling.

**Insulinoma**

Insulinomas are the most common functional pancreatic endocrine neoplasms and present with a typical clinical syndrome known as Whipple’s triad. The triad consists of symptomatic fasting hypoglycemia, a documented serum glucose level <50 mg/dL, and relief of symptoms with the administration of glucose. Patients can present with a profound syncopal episode or less severe symptoms that are averted by frequent eating. Common symptoms include palpitations, trembling, diaphoresis, confusion or obtundation, and seizure, and family members may report that the patient has undergone a personality change.

Routine laboratory studies will uncover a low blood sugar, the cause of all of these symptoms. Serum insulin levels are elevated. C-peptide levels should also be elevated and rule out the unusual case of surreptitious administration of insulin or oral hypoglycemic agents, because excess endogenous insulin production leads to excess C-peptide. The diagnosis can be clinched with a monitored fast in which blood is sampled every 4 to 6 hours for glucose and insulin levels until the patient becomes symptomatic. However, this can be dangerous and must be done with close supervision.

Insulinomas are usually localized with CT scanning and EUS. Technical advances in EUS have led to preoperative identification of >90% of insulinomas. Visceral angiography with venous sampling is rarely required to accurately localize the tumor. Insulinomas are evenly distributed throughout the head, body, and tail of the pancreas.

Unlike most endocrine pancreatic tumors, the majority (90%) of insulinomas are benign and solitary, and only 10% are malignant. They are typically cured by simple enucleation. However, tumors located close to the main pancreatic duct and large (>2 cm) tumors may require a distal pancreatectomy or pancreaticoduodenectomy. Intraoperative US is useful to determine the tumor’s relation to the main pancreatic duct and guides intraoperative decision making. Enucleation of solitary insulinomas and distal pancreatectomy for insulinoma can sometimes be performed using a minimally invasive technique.

Approximately 90% of insulinomas are sporadic, and 10% are associated with the MEN1 syndrome. Insulinomas associated with the MEN1 syndrome are more likely to be multifocal and have a higher rate of recurrence.

**Noninsulinoma Hyperinsulinemia**

**Hypoglycemia Syndrome**

A syndrome of noninsulinoma pancreatogenous hypoglycemia was described by Service et al. in 1999. The syndrome is associated with beta-cell hypertrophy, islet hyperplasia and increased beta-cell mass. When these findings are accompanied by ectopic islet tissue, multilobulated islets, and ductulo-insular complexes, the definition of nesideoblastosis is met. Nesideoblastosis accompanied by hyperinsulinism was previously considered a disease of neonates, where subtotal or total pancreatectomy was required to correct potentially fatal neonatal hyperinsulinism. However, dozens of cases of nesideoblastosis associated with hyperinsulinism have now been reported in patients 2 to 5 years after Roux-en-Y gastric bypass. Many of these patients have undergone partial or total pancreatectomy to prevent potentially fatal hypoglycemia. The illness in former bariatric surgery patients appears to result from an idiiosyncratically-prolonged hypersecretion of the incretin hormones GIP and GLP-1 after the gastric bypass. GLP-1 is a potent stimulant of the expression of the transcription factor PDX-1, which normally regulates beta-cell development and growth. Conversion of the gastric bypass to a form of bariatric procedure which restores normal intestinal flow of nutrients, such as the gastric sleeve, or the addition of a restriction element such as an adjustable gastric band, appears to prevent episodes of hypoglycemia in these patients. Pancreatic resection without conversion of the Roux-en-Y gastric bypass allows the abnormal entero-insular relationship to continue, and hyperinsulinemia persists or recurs after partial pancreatectomy.

**Gastrinoma**

Zollinger-Ellison syndrome (ZES) is caused by a gastrinoma, an endocrine tumor that secretes gastrin, leading to acid hypersecretion and peptic ulceration. Many patients with ZES present with abdominal pain, peptic ulcer disease, and severe esophagitis. However, in the era of effective antacid therapy, the presentation can be less dramatic. Although most of the ulcers...
are solitary, multiple ulcers in atypical locations that fail to respond to antacids should raise suspicion for ZES and prompt a work-up. At the time of diagnosis, 21% of patients with gastrinoma have diarrhea.

The diagnosis of ZES is made by measuring the serum gastrin level. It is important that patients stop taking proton pump inhibitors for this test. In most patients with gastrinomas, the level is $>1000$ pg/mL. Gastrin levels can be elevated under conditions other than ZES. Common causes of hypergastrinemia include pernicious anemia, treatment with proton pump inhibitors, renal failure, G-cell hyperplasia, atrophic gastritis, retained or excluded antrum, and gastric outlet obstruction. In equivocal cases, when the gastrin level is not markedly elevated, a secretin stimulation test is helpful.

In 70% to 90% of patients, the primary gastrinoma is found in Passaro’s triangle, an area defined by a triangle with points located at the junction of the cystic duct and common bile duct, the second and third portion of the duodenum, and the neck and body of the pancreas (Fig. 33-63). However, because gastrinomas can be found almost anywhere, whole-body imaging is required.

The test of choice is SSTR (octreotide) scintigraphy in combination with CT. The octreotide scan is more sensitive than CT, locating about 85% of gastrinomas and detecting tumors $<1$ cm. With the octreotide scan, the need for tedious and technically demanding selective angiography and measurement of gastrin gradients has declined. EUS is another modality that assists in the preoperative localization of gastrinomas. It is particularly helpful in localizing tumors in the pancreatic head or duodenal wall, where gastrinomas are usually $<1$ cm in size. A combination of octreotide scan and EUS detects $>90\%$ of gastrinomas.

It is important to rule out MEN1 syndrome by checking serum calcium levels before surgery because resection of the gastrinoma(s) in these patients rarely results in normalization of serum gastrin concentrations or a prolongation of survival. Only one fourth of gastrinomas occur in association with the MEN1 syndrome. One half of patients with gastrinomas will have solitary tumors while the remainder will have multiple gastrinomas. Multiple tumors are more common in patients with MEN1 syndrome. Aggressive surgical treatment is justified in patients with sporadic gastrinomas. If patients have MEN1 syndrome, the parathyroid hyperplasia is addressed with total parathyroidectomy and implantation of parathyroid tissue in the forearm.

Approximately 50% of gastrinomas metastasize to lymph nodes or the liver, and are therefore considered malignant. Patients who meet criteria for operability should undergo exploration for possible removal of the tumor. Although the tumors are submucosal, a full-thickness excision of the duodenal wall is performed if a duodenal gastrinoma is found. All lymph nodes in Passaro’s triangle are excised for pathologic analysis. If the gastrinoma is found in the pancreas and does not involve the main pancreatic duct, it is enucleated. Pancreatic resection is justified for solitary gastrinomas with no metastases. A highly selective vagotomy can be performed if unresectable disease is identified or if the gastrinoma cannot be localized. This may reduce the amount of expensive proton pump inhibitors required. In cases in which hepatic metastases are identified, resection is justified if the primary gastrinoma is controlled and the metastases can be safely and completely removed. Debulking or incomplete removal of multiple hepatic metastases is probably not helpful, especially in the setting of MEN1. The application of new modalities such as radiofrequency ablation seems reasonable, but data to support this approach are limited. Postoperatively, patients are followed with fasting serum gastrin levels, secretin stimulation tests, octreotide scans, and CT scans. In patients found to have inoperable disease, chemotherapy with streptozocin, doxorubicin, and 5-fluorouracil (5-FU) is used. Other approaches such as somatostatin analogues, interferon, and chemoembolization also have been used in gastrinoma with some success.

Unfortunately, a biochemical cure is achieved in only about one-third of the patients operated on for ZES. Despite the lack of success, long-term survival rates are good, even in patients with liver metastases. The 15-year survival rate for patients without liver metastases is about 80%, while the 5-year survival rate for patients with liver metastases is 20% to 50%. Pancreatic tumors are usually larger than tumors arising in the duodenum, and more often have lymph node metastases. In gastrinomas, liver metastases decrease survival rates, but lymph node metastases do not. The best results are seen after complete excision of small sporadic tumors originating in the duodenum. Large tumors associated with liver metastases, located outside of Passaro’s triangle, have the worst prognosis.

**Vasoactive Intestinal Peptide-Secreting Tumor**

In 1958, Verner and Morrison first described the syndrome associated with a pancreatic neoplasm secreting VIP. The classic clinical syndrome associated with this pancreatic endocrine neoplasm consists of severe intermittent watery diarrhea leading to dehydration, and weakness from fluid and electrolyte losses. Large amounts of potassium are lost in the stool. The *vasoactive intestinal peptide-secreting tumor (VIPoma)* syndrome is also called the WDHA syndrome due to the presence of watery diarrhea, hypokalemia, and achlorhydria. The massive (5 L/d) and episodic nature of the diarrhea associated with the appropriate electrolyte abnormalities should raise suspicion of the diagnosis. Serum VIP levels must be measured on multiple occasions because the excess secretion of VIP is episodic and single measurements might be normal and misleading. ACT scan localizes most VIPomas, although as with all islet cell tumors, EUS is the most sensitive imaging method. Electrolyte and fluid balance
is sometimes difficult to correct preoperatively and must be pursued aggressively. Somatostatin analogues are helpful in controlling the diarrhea and allowing replacement of fluid and electrolytes. VIPomas are more commonly located in the distal pancreas and most have spread outside the pancreas. Palliative debulking operations can sometimes improve symptoms for a period, along with somatostatin analogues. Hepatic artery embolization also has been reported as a potentially beneficial treatment.282

**Glucagonoma**

Diabetes in association with dermatitis should raise the suspicion of a glucagonoma. The diabetes usually is mild. The classic necrolytic migratory erythema manifests as cyclic migrations of lesions with spreading margins and healing centers typically on the lower abdomen, perineum, periportal area, and feet. Patients also complain of an enlarged, sensitive tongue. The diagnosis is confirmed by measuring serum glucagon levels, which are usually >500 pg/mL. Glucagon is a catabolic hormone, and most patients present with malnutrition. The rash associated with glucagonoma is thought to be caused by low levels of amino acids. Preoperative treatment usually includes control of the diabetes, parenteral nutrition, and octreotide. Like VIPomas, glucagonomas are more often in the body and tail of the pancreas and tend to be large tumors with metastases. Again, debulking operations are recommended in good operative candidates to relieve symptoms.

**Somatostatinoma**
